CONTENTS

PREFACE

We are honored to contribute to the information and education of ophthalmology students around the world. We have attempted to distill the current knowledge of medical practice and basic science retina research into a diagnostic atlas of retinal diseases. This is a quick-reference atlas eBook of the retina, edited by specialists in the field, essential to any practicing ophthalmologist or resident who has more than a passing interest in diseases and treatment of the retina.

This e-book includes contributors from Mexico, Venezuela, Argentina, Brazil, United States, Denmark, Spain, Italy, Costa Rica and Peru. It is divided into three volumes: Volume I, retinal vascular diseases, choroidal neovascularization related diseases, vitreomacular interface, and other macular disorders; Volume II, traumatic retinopathies, diseases of vitreous, peripheral degenerations, retinal detachment, pediatric retinal diseases, and retinal dystrophies; and Volume III, posterior uveitis, tumors of the retina and choroid.

This diagnostic atlas eBook of retinal diseases contains full-color, high quality images of the most frequent retinal pathologies with a brief and comprehensive review of retinal diseases. Each chapter includes essentials of diagnosis, differential diagnosis and treatment. The format is concise, well organized, and didactic, without being exhaustive.

We hope and expect that our atlas of retina will facilitate in providing patients with the best pos-sible care.

ACKNOWLEDGEMENTS

We would like to express our gratitude to Judy Soriano, who provided support with english composition and edition.

To our friends and colleagues without whose contribution would not have been possible to realize this project.

We also want to thank the staff of Bentham Science for their help and support and give us the opportunity to publish this eBook.

DEDICATION

This e-book is specially dedicated to Guillermo Manuel Gordon, MD. He inspired us to always work hard and try our best. He was a friend and a recognized ophthalmologist of Rosario-Argentina, who died on May 2nd, 2015.

CHAPTER 1

Commotio Retinae

Matteo Forlini*

Retina Department, Institute of Ophthalmology, University of Modena, Modena, Italy

The term commotio retinae describes a whitish or yellowish discoloration of the retina after blunt trauma. It is caused by shock waves that traverse the eye from the site of impact. The mechanism by which the retina acquires this appearance is uncertain, but extracellular edema, glial swelling or disruption of the photoreceptor outer segments have been proposed as potential causes. There is little to no intercellular edema [1, 5, 7].

ESSENTIALS OF DIAGNOSIS

- Decreased vision or asymptomatic.
- History of recent ocular trauma.
- A sheenlike retinal whitening is observed, appearing several hours after injury (confluent area of retinal whitening, gray opacification of the retina) (Fig. **1**).
- Commotio can occur to peripheral retina (most frequently it affects the temporal fundus) or the central macular region; commotio retinae in the posterior pole is also called *Berlin edema* [1 - 9] (Fig. **1**).
- If the macula is involved, a "cherry-red spot" may be seen at the fovea, because the cells involved in the whitening are not present in the fovea (Fig. **1**).
- Retinal blood vessels are unaffected. However, other signs of ocular trauma may be seen, such as intraretinal or vitreous hemorrhage.
- Visual acuity does not always correlate with the degree of commotio retinae [1 - 9].
- Sequelae to more severe commotio may include progressive pigmentary degeneration, choroidal rupture, or macular hole formation [2, 5 - 9].

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

Fig. (1). Color fundus photograph. Commotio retinae.

DIFFERENTIAL DIAGNOSIS

- The patient should also be evaluated for serous retinal detachment, which also diminishes the prognosis for vision recovery.
- Branch retinal artery occlusion (whitening of the retina along the distribution of an artery) should be excluded, even though it rarely follows trauma.
- "White without pressure" (a common peripheral retinal finding) could also present with retinal whitening; it may be associated with a prominent vitreous base.
- Considerable damage to the retinal pigment epithelium can occur, eventually leading to granular pigmentation and bone corpuscular appearance of the

affected retina resembling retinitis pigmentosa.

MANAGEMENT

- Complete ophthalmic evaluation, including dilated fundus examination with scleral depression should be performed (or without scleral depression if a ruptured globe, hyphema, or iritis is present).
- Commotio retinae may decrease visual acuity to as low as 20/200, or even less. Fortunately the prognosis in mild cases, with no associated complications, is good with spontaneous resolution within 3-4 weeks. No treatment is required. Rarely, some patients with foveal involvement may be left with chronic visual impairment secondary to photoreceptor damage.
- Dilated fundus examination is repeated in 1 to 2 weeks. Patients should be educated about the symptoms of retinal detachment and instructed to return sooner if present [1 - 9].

CONFLICT OF INTEREST

The author confirms that author has no conflict of interest to declare for this publication.

CHAPTER 2

Choroidal Rupture

Francys J. Torres Méndez[1,2] and **Mitzy E. Torres Soriano**[3,*]

[1] *Hospital los Samanes, Centro Oftalmológico Regional Aragua (CORA), Maracay, Venezuela*

[2] *Clínica de Ojos Aragua, Maracay, Venezuela*

[3] *Centro de la Visión Gordon-Manavella, Rosario, Santa Fe, Argentina*

The choroid is the external vascular layer lying between the retina and the sclera [1]. Its thickest part is in the posterior pole (0.22 mm) and it narrows towards the ora serrata to 0.1 mm. The choroid's main function is the vascular supply to the retinal pigment epithelium (RPE) that comes from the internal carotid artery and the ophthalmic artery, and drains into the vortex veins, determining the color of the ocular fundus [2, 3].

The suprachoroidal space is a virtual space. Pathologically, the choroidal rupture is a break in the Bruch membrane and the RPE. Unlike the retina and the sclera, which can resist several impacts thanks to their strength and elasticity, choroidal ruptures occur in 8% of patients who suffer blunt trauma and they are caused by an anteroposterior compression of the globe with expansion in the horizontal plane [3].

ESSENTIALS OF DIAGNOSIS

Initially, a choroidal rupture may be difficult to diagnose because it may be obscured by associated vitreous, intra- or subretinal hemorrhages. Hemorrhages caused by choroidal rupture are characterized by regular, sharply-defined edges, which indicates they are located in the sub retina or the choroid [2].

* **Corresponding author Mitzy E. Torres Soriano:** Centro de la Visión Gordon - Manavella, Montevideo 763, CP 2000, Rosario - Santa Fe, Argentina; Tel/Fax: +54 (341) 4400239/4244850; E-mail: mitzytorres@yahoo.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

Choroidal ruptures can develop in two ways: Indirect ruptures are evidenced at an early stage with choroidal or retinal hemorrhages. After hemorrhages are resolved, the typical crescent-shaped lesions become visible (Fig. **1**), similar to a fundoscopic image of angioid streaks, (Fig. **2**) concentric and concave to the optic disc and, most frequently, in the inter papillo-macular region [4]. In other cases, lesions are located around the optic disc, corresponding to traumatic peripapillary choroidopathy, which can lead to optic atrophy [6]. Direct ruptures are located at the site of trauma, involve hemorrhage and oedema, and, only after hemorrhage is resolved, the atrophic site becomes visible surrounded by pigmentation [4].

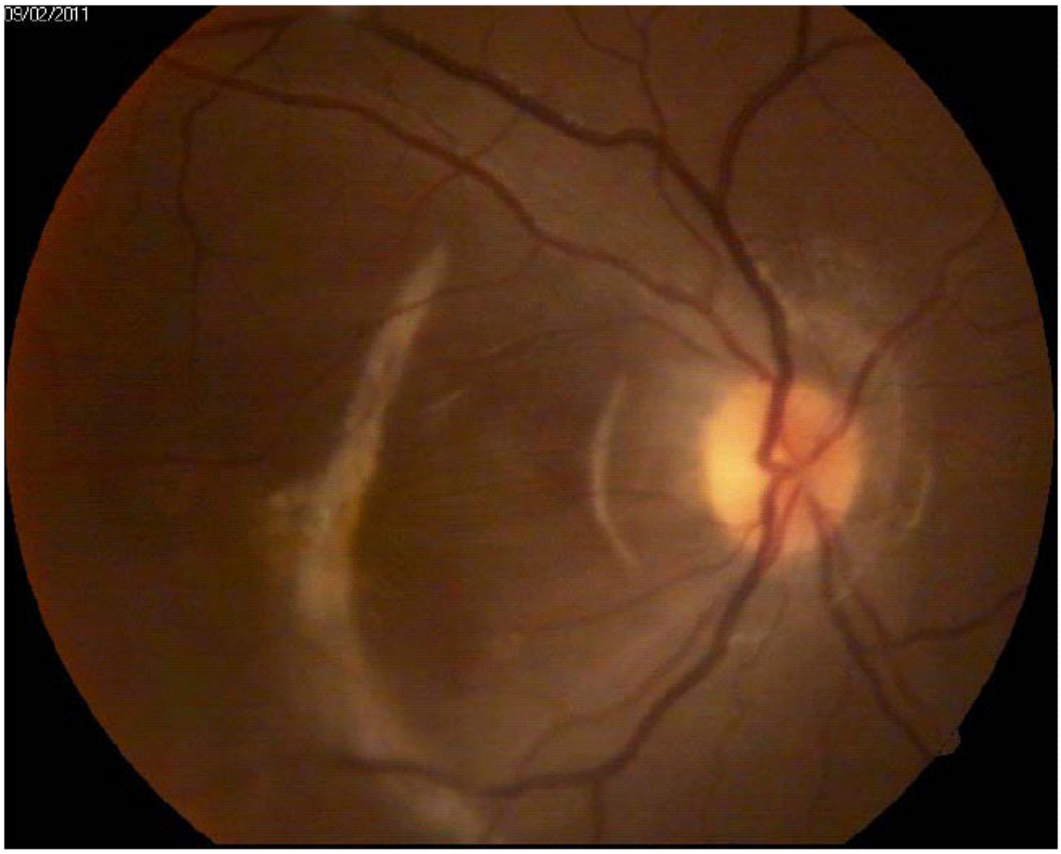

Fig. (1). Colour fundus photograph. Choroidal rupture (Courtesy of Ophthalmology Department, Hospital Central de Maracay, Venezuela).

Fig. (2). Angioid streaks, a mixture of brownish streaks, pale atrophic areas, mainly around the margin of the optic disc, curved streaks concentric with the disc that are reminiscent of traumatic choroidal rupture lines (Courtesy of Michael Larsen, MD, Copenhagen, Denmark).

The visual prognosis depends mainly on the location of the injury. The histopathological process of choroidal rupture repair is completed 3 weeks after trauma and is accompanied by the formation of a well-established scar. This tissue process includes fibroblastic activity and RPE hyperplasia at the edges of the lesion. Choroidal neovascularization can develop from choroidal rupture in approximately 10-20% of cases during the scarring process [5].

Diagnosis is made based on clinical findings: clinical record, clinical interview,

CHAPTER 3

Traumatic Macular Hole

Jose Dalma-Weiszhausz[*, 1] and **Gerardo García-Aguirre**[1,2]

[1] *Attending Physician, Retina Department, Asociación para Evitar la Ceguera en Mexico, Mexico City, Mexico*

[2] *Escuela de Medicina, Tecnológico de Monterrey, Mexico City, Mexico*

Macular holes secondary to blunt ocular trauma are not an uncommon event and may appear almost immediately after a contusion although they have also been reported after a severe electric shock and accidental laser injury. The true incidence is unknown but traumatic macular holes (TMH) comprise about 10% of all macular holes [1].

ESSENTIALS OF DIAGNOSIS

Clinical characteristics of traumatic macular holes differ somewhat from the idiopathic variety. They tend to be larger (300-1000μ) [2], irregularly shaped and often associated with other pathologic traumatic findings, *i.e.*: commotion retinae, choroidal ruptures, angle recession, hyphema and/or vitreous hemorrhage (Fig. **1**). Visual acuity tends to range from 20/100 to 10/800 [3].

The pathophysiology responsible for macular hole formation is uncertain. Several mechanisms have been proposed including acute antero-posterior vitreous traction, contusional retinal necrosis and tangential traction from the internal limiting membrane. Since posterior vitreous detachment is seldom observed in these patients we believe that the most plausible explanation is that a sudden deformation of the globe during blunt trauma tends to stretch the posterior pole causing a rupture of the fairly inelastic internal limiting membrane producing tangential traction on the thinnest part of the retina [4, 5]. Sometimes the hole

[*] **Corresponding author Jose Dalma-Weiszhausz:** Vicente García Torres 46, San Lucas Coyoacan, Mexico City, Mexico, 04030; Tel: +52 (55) 10841400; E-mail: josedalma@gmail.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

appears weeks after the traumatic event in which case the initial tear is probably acute but the traction appears later, perhaps associated with epiretinal membrane formation. TMHs, as the idiopathic variety, are seldom associated with large retinal detachments. If a detachment is observed, a peripheral retinal break should be sought.

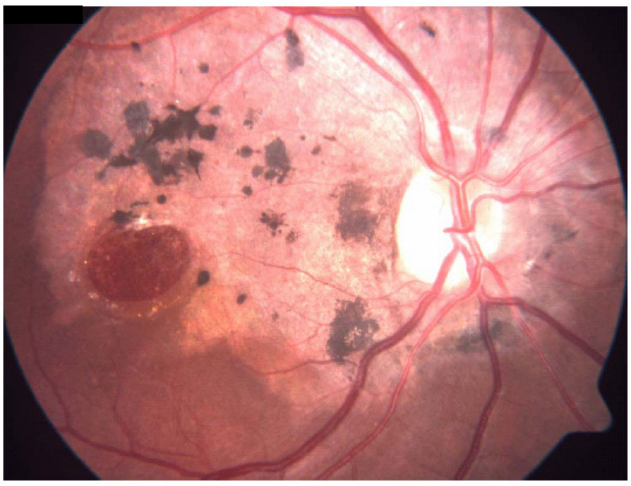

Fig. (1). Colour fundus photograph of a right eye four months after blunt trauma. A large macular hole and severe pigment changes can be observed.

The diagnosis of traumatic macular hole is pretty straightforward most of the times. It can be seen clinically, and easily confirmed by optic coherence tomography (OCT).

DIFFERENTIAL DIAGNOSIS

Differential diagnosis should be made with contusion of the retinal pigment epithelium, submacular hemorrhage, epiretinal membrane with macular pseudohole or lamellar macular hole. An OCT is usually sufficient to make the correct diagnosis.

MANAGEMENT

Management of traumatic macular holes, as of the early 1990's, is surgical. Pars plana vitrectomy with posterior hyaloid removal has proven to be highly beneficial in the majority of patients. Although internal limiting membrane (ILM)

removal is controversial, most authors report better anatomical and visual results [5, 6]. Since most patients tend to be young, some steps in the procedure are not easy. Posterior hyaloid removal is often difficult and requires patience. It is important to avoid iatrogenic retinal trauma on ILM dissection. The use of appropriate forceps and dye to stain it for better visibility is a must. Presently, brilliant blue dye appears to be the colorant of choice although not approved in some countries (Figs. **2**-**4**). Gas tamponade and postoperative positioning at least for a few days appear to improve the anatomical success rate. Often adequate positioning is hampered by associated injuries or physical state. Silicone oil tamponade should be considered in these circumstances. Autologous platelets as an adjunct to ILM peeling in macular hole repair may enhance chronic macular hole closure in patients unable to maintain prone positioning [7]. Anatomical results are good although visual results may be modest, mostly due to associated traumatic eye pathology. We've found that the exception is TMH closely associated with choroidal fractures where the fibrosis associated with the rupture precludes hole closure. This fibrosis is often very hard and involves the retina making it impossible for it to release. A few cases have been reported of spontaneous hole closure [8]. This seems to be a rare occurrence and the possibility should not preclude or delay surgical therapy.

Fig. (2). Still photograph from an intraoperative video showing profuse submacular hemorrhage and a macular hole.

CHAPTER 4

Purtscher's Retinopathy

Matteo Forlini[1,*] and **Cesare Forlini**[†]

[1] *Retina Department, Institute of Ophthalmology, University of Modena, Modena, Italy*

Purtscher's retinopathy is a retinal vaso-occlusive and hemorrhagic vasculopathy, usually associated with head trauma or thoracic compression.

Even if the real cause is not well understood, the most likely pathogenic process is an embolic obstruction of the precapillary arterioles in the retina [1-4].

ESSENTIALS OF DIAGNOSIS

- Sudden visual loss, hours to days after trauma (variable severity).
- Unilateral or bilateral involvement.
- Patognomonic findings concentrated in the peripapillary area.
- Cotton-wool spots (Fig. **1**).
- Intraretinal hemorrhages and exudates (Fig. **1**).
- Retinal edema.
- "Purtscher flecken", resulting from precapillary arterioles occlusion (50% of cases, pathognomonic).
- Optic atrophy as late finding.

DIFFERENTIAL DIAGNOSIS

- Purtscher's like retinopathy: similar retinal findings, associated to a wide spectrum of systemic diseases, such as acute pancreatitis (Fig. **1**), long bone fracture, amniotic fluid embolism or fat embolism, hemolysis, vasculitic diseases (collagen vascular purpura, lupus) [1, 2].

[*] **Corresponding author Matteo Forlini:** Retina Department, Institute of Ophthalmology, University of Modena, Modena, Italy; Tel: +39 3395656062; E-mail: matteoforlini@gmail.com

[†] Deceased.

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

- Central retina artery/vein occlusion: fundus findings seem to be the same, but no history of trauma.

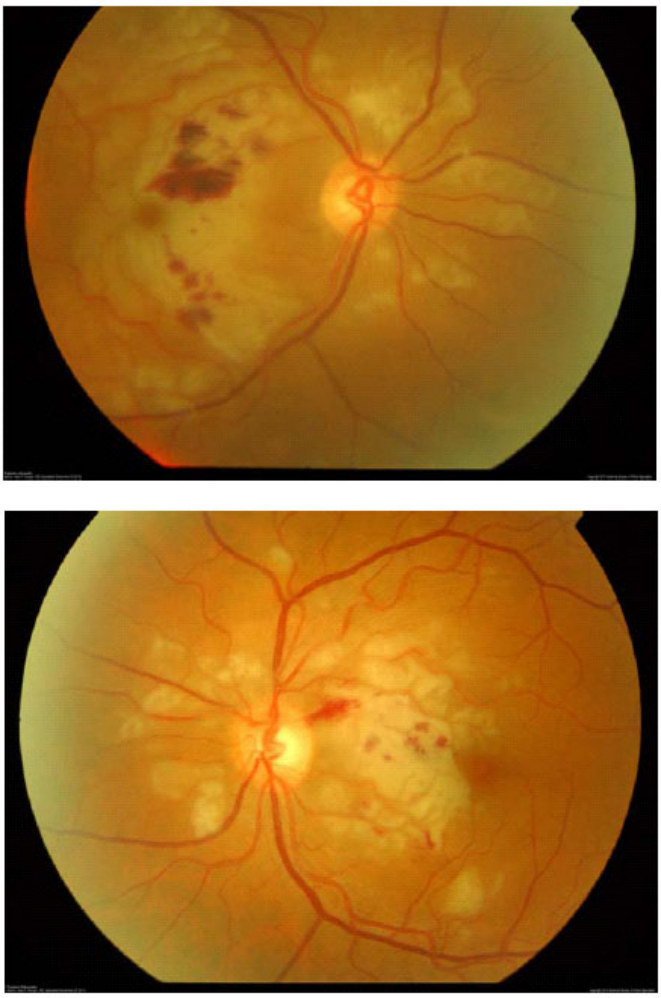

Fig. (1). Fundus photographs (right and left eye) of a 63-year-old male with alcoholic pancreatitis and Purtscher retinopathy (This image was originally published in the ASRS Retina Image Bank. Alex P. Hunyor, MD. Purtscher Retinopathy. Retina Image Bank. 2015; Image Number 2921 and 2922. © the American Society of Retina Specialists).

MANAGEMENT

- Fluorescein angiography: retinal ischemia areas.
- Optical coherence tomography: edema of the nerve fiber layer and subretinal fluid.

- CT imaging of chest and long bones if necessary.
- Permanent visual loss may occur in half of affected eyes; no treatment available [1, 3 - 7].

CONFLICT OF INTEREST

The author confirms that author has no conflict of interest to declare for this publication.

ACKNOWLEDGEMENTS

Declared none.

CHAPTER 5

Terson Syndrome

Adai Pérez Montesinos[1,2,*]

[1] *Clínica Almendros, Oaxaca, Mexico*

[2] *Ophthalmology Service of Hospital, Regional de Alta Especialidad de Oaxaca, Mexico*

Terson described in 1900 [1] an intraocular hemorrhage in association with subarachnoid bleed or subdural hemorrhage [2]. The syndrome of vitreous hemorrhage in association with any form of intracranial hemorrhage has come to be known as Terson's syndrome. The most common cause of Terson's syndrome is acute subarachnoid hemorrhage resulting from a ruptured intracranial aneurysm [3].

ESSENTIALS OF DIAGNOSIS

Terson's syndrome is more common than usually thought. It has been found to occur in 3% to 8% of individuals with subarachnoid hemorrhage. However, the urgency of managing a serious intracranial hemorrhage usually supersedes fundoscopic examination by a retina specialist.

Bilateral, intraretinal, and subretinal hemorrhages can be observed (Figs. **1** and **2**). Pre-retinal hemorrhage may occur within the temporal vascular arcades, forming a peculiar dome-shaped accumulation of blood [4]. This blood, which has accumulated between the internal limiting membrane and posterior hyaloid face, may disperse into the vitreous. The partially detached posterior hyaloids in some longstanding cases provides a scaffold for cellular proliferation and the development of an elevated epiretinal membrane. A high incidence of macular

[*] **Corresponding author Adai Pérez Montesinos:** Calle Almendros, Col. Reforma, 68050, Oaxaca, Oaxaca, Mexico; Tel: +52 951-515-6087; E-mail: adaipm@hotmail.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

abnormalities, including hemorrhagic cysts and epiretinal membranes, has been reported [3, 4].

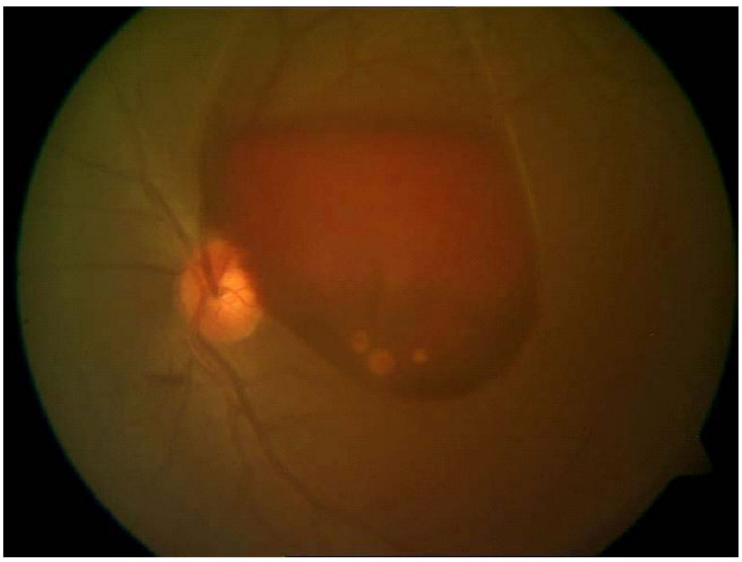

Fig. (1). Fundus photograph of a 31-year-old male with history of recent blunt head trauma, showing media opacities secondary to vitreous hemorrhage, and the presence of a subhyaloid hemorrhage.

The exact pathogenesis of Terson's syndrome is unknown. One report suggested that it was caused by the dissection of blood from the subarachnoid space through the optic nerve sheath and into the eye [5]. However, there is no direct communication between the subarachnoid space and the vitreous cavity in the normal eye, and hemorrhage that is not contiguous with the optic disc can be seen in this condition [4]. A more plausible explanation suggests that an acute rise in intracranial pressure, such as the one that occurs with intracranial hemorrhage, is transmitted down the sub-arachnoid space of the optic nerve, causing venous stasis *via* compression and stretching of the intra-orbital veins. This, in turn, causes a rapid rise in intraocular venous pressure, distention, and rupture of the fine papillary and retinal capillaries and subsequent vitreous hemorrhage.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis should be made with other traumatic retinopathies, such as Purtscher's retinopathy, which is associated to compressive injury to the thorax

and head, causing a characteristic retinopathy with intraretinal hemorrhage and cotton-wool spots, or Valsalva retinopathy, which is caused by a sudden rise in intra-thoracic or intra-abdominal pressure, causing rupture of capillaries in the macula and subsequent hemorrhage beneath the internal limiting membrane. Other differential diagnoses to consider are shaken baby syndrome and anemic retinopathy.

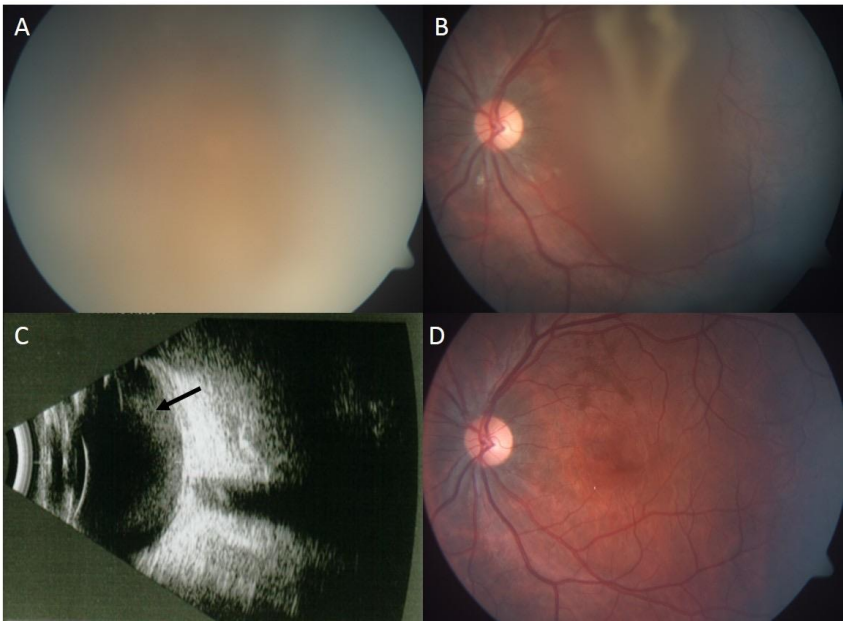

Fig. (2). (**A**). Fundus photograph of the left eye of a 23-year-old male patient with history of blunt head trauma and a subarachnoid hemorrhage showing vitreous hemorrhage. (**B**). Partial reabsorption of the hemorrhage. (**C**). B-scan Ultrasound showing subhyaloid hemorrhage. (**D**). Fundus photograph after pars-plana vitrectomy, showing remnants of subretinal hemorrhage (Images courtesy of Javier Flores-Preciado, MD).

MANAGEMENT

Observation is a management option for vitreous hemorrhage, especially in adults with unilateral involvement. Vitreous hemorrhage in Terson's syndrome usually clears within a year but may take longer [2]. However, surgical intervention is advised to avoid potential complications of persistence of blood in the vitreous such as epiretinal membranes, other macular abnormalities, and retinal detachment, as well as amblyopia and myopia in infants. Several reports have

Valsalva retinopathy is a rare condition that causes a sudden loss of visual acuity. It was first described by Duane in 1972 as a preretinal hemorrhage [1].

ESSENTIALS OF DIAGNOSIS

It may occur as a sudden, dramatic loss of central vision due to the premacular location of the hemorrhage, caused by a rapid increase in intraocular venous pressure as a consequence of valsalva´s maneuver [2]. This maneuver is a forcible exhalation effort against a closed glottis, caused by a sudden rise in intra-thoracic and intra-abdominal pressure, which raises the central venous pressure. There are no valves in the venous rostral system towards the heart, so a rise in the reflux venous pressure may occur in the head and neck region of the body. This unexpected increase in the venous pressure can rupture the perimacular vessels resulting in premacular hemorrhage [3].

The location of the bleeding can differ according to the magnitude of the hemorrhage. The preretinal structures are closely appose to the retinal surface in young adults, although hemorrhage can dissect tissue plane and fill the potential spaces. The most common location is in the subinternal limiting membrane [4]. It can also be present in the subhyaloid or in a combination of both (Figs. **1** and **2**). Vitreous hemorrhage and subretinal hemorrhage have also been described.

Fig. (1). A 26-year-old male with a sudden loss of visual acuity (HM) in right eye, as a consequence of valsalva´s maneuver. Fundus photograph shows preretinal hemorrhage (Courtesy of Retinal Camera, Ophthalmology Department, Hospital Central de Maracay, Venezuela).

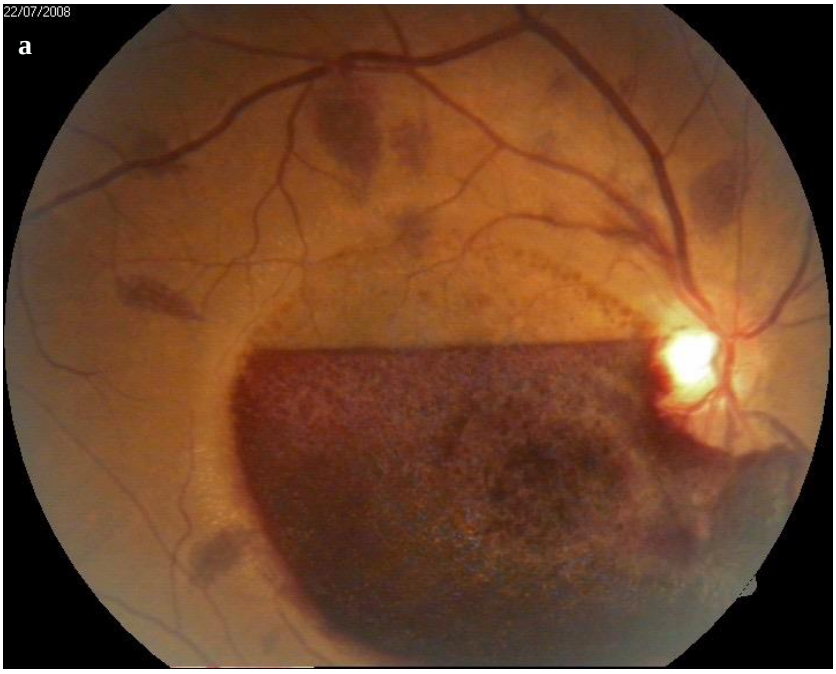

Fig. 2 contd.....

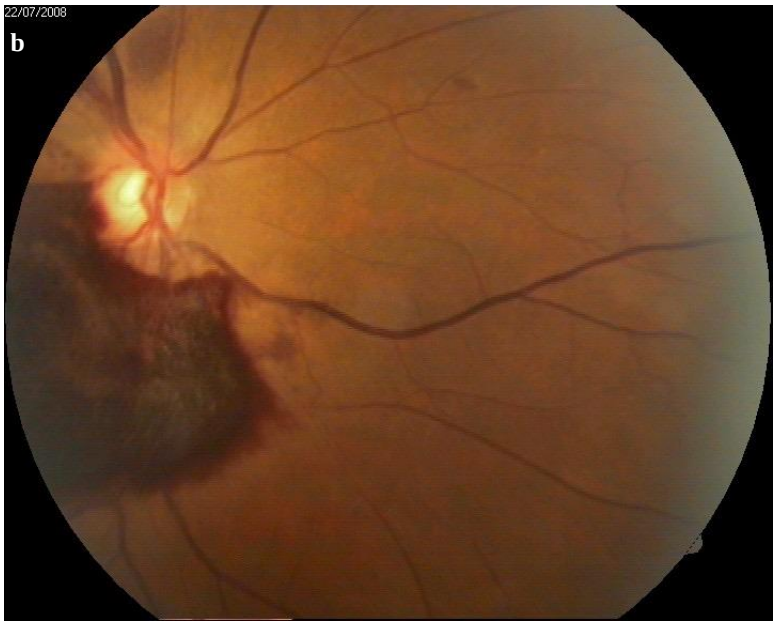

Fig. (2). (**a**) and (**b**) Woman of 45 years old with a massive subinternal limiting membrane hemorrhage in right eye, secondary to valsalva maneuver. Visual acuity: hand motion (Courtesy of Mitzy Torres Soriano, MD).

It often occurs in healthy young male adults as a result of a variety of clinical settings. However, its recurrence is infrequent.

Risk factors that can contribute to this condition:

Intense aerobic exercise, heavy lifting, balloon inflation, straining on the toilet, bout of vomiting (such as in pregnancy or bulimia), bout of coughing [5], thoracoabdominal trauma, vigorous sexual activity [1], choking games, vigorous dancing, and colonoscopy complication [6].

DIFFERENTIAL DIAGNOSIS

It is imperative to exclude systemic disease such as diabetes, hypertension and ocular vein occlusion. Hematological conditions such as sickle cell disease, anemia, coagulopathies, and blood dyscrasias, trauma, infection diseases, degenerations, cancer, rupture retinal macroaneurysm and shaken baby syndrome [7].

CHAPTER 7

Chorioretinitis Sclopetaria

Matteo Forlini[*] and **Caterina Benatti**

Retina Department, Institute of Ophthalmology, University of Modena, Modena, Italy

Chorioretinitis sclopetaria is a term used to describe a full-thickness retinal and choroidal lesion caused by a high-velocity projectile passing through the orbit without perforating the sclera.

Chorioretinal injury is due to shock waves produced by the missile's passage through the orbit [1 - 3].

ESSENTIALS OF DIAGNOSIS

- Decreased vision (severity depending on region involved).
- History of recent ocular high-velocity penetrating trauma (missile/projectile).
- Subretinal, intraretinal, preretinal hemorrhage, often involving posterior pole.
- Vitreous hemorrhage or vitreous base avulsion, which can lead to peripheral retinal dialysis or retinal tears.
- Choroid and retina ruptures, with underlying bare sclera.
- White fibrous scar and RPE changes, usually in the peripheral retina, when blood is resorbed (Fig. **1**).
- Claw-like break of Bruch membrane [1 - 4].

DIFFERENTIAL DIAGNOSIS

- Ruptured globe: Poor visual acuity, presence of relative afferent pupillary defect (RAPD), subconjunctival hemorrhage and chemosis, irregular pupil, low IOP.

[*] **Corresponding author Matteo Forlini:** Retina Department, Institute of Ophthalmology, University of Modena, Modena, Italy; Tel: +39 3395656062; E-mail: matteoforlini@gmail.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

- Choroidal rupture: Break in the choroid, Bruch membrane, RPE, following a closed globe injury from blunt trauma. Neurosensory retina is not involved. A posterior pole retinal hemorrhage could obscure a choroidal rupture until blood clears after few weeks.
- Optic nerve avulsion: Decreased vision with RAPD, vitreous hemorrhage with hemorrhagic depression or excavation of the optic disc, or retraction of entire nerve if severe. Poor visual prognosis, no treatment.

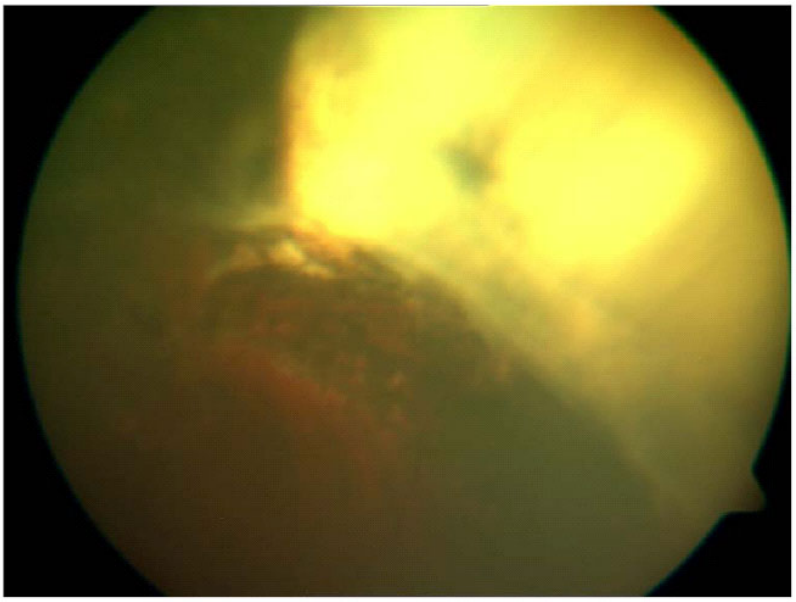

Fig. (1). Chorioretinitis sclopetaria. Fundus photograph showing white fibrous scar and RPE changes in the peripheral retina, one month after blunt trauma with a high pressure water gun (Courtesy of Maximiliano Gordon, MD).

MANAGEMENT

- Complete ophthalmic evaluation, including dilated fundus examination, anterior segment examination, conjunctiva and anterior sclera (check if ruptured globe).
- CT / B-scan or UBM if high risk of intrascleral, intraocular, or intraorbital foreign bodies.
- Follow up examination every 2-4 weeks until blood is resorbed and fibrous changes appear [5 - 7].
- In certain cases, surgery for retinal detachment or nonclearing vitreous hemorrhage may be needed.

CONFLICT OF INTEREST

The author confirms that author has no conflict of interest to declare for this publication.

ACKNOWLEDGEMENTS

Declared none.

CHAPTER 8

Posterior Vitreous Detachment

Fernando Miassi[1,2] and **Veronica Kon Graversen**[3,*]

[1] *Retina Department, Clínica Retina Rosario, Rosario, Santa Fe, Argentina*

[2] *Ophthalmology Department, Sanatorio Centro, Rosario, Santa Fe, Argentina*

[3] *University of North Carolina at Chapel Hill, NC, USA*

Posterior vitreous detachment (PVD) is a physiological phenomenon in which the posterior vitreous cortex separates from the internal limiting membrane of the retina. Two progressive age-related alterations of the vitreous result in PVD: vitreous liquefaction and weakening of the vitreoretinal adhesion [1]. The detachment occurs between ages of 50 and 70 in general population, but may occur earlier in highly myopic patients [2]. Snead *et al.* [2] report the prevalence of PVD to be 57% in a randomly selected group of normal subjects. In most patients, PVD has no important consequences. However, especially in eyes with abnormally high vitreoretinal adherence, it may lead to symptomatic retinal breaks, and eventually cause a rhegmatogenous retinal detachment (RRD) [3]. The PVD is considered "complete" when the vitreous cortex is not attached to either the fovea or the optic nerve and "incomplete" when is at least partially attached to one of them.

ESSENTIALS OF DIAGNOSIS

Photopsia: Usually more apparent in the dark, as a consequence of vitreous traction exerted over the retina by the vitreous. This phenomena is recognized in the absence of outside light stimulation.

* **Corresponding author Veronica Kon Graversen:** Ophthalmology Department, University of North Carolina at Chapel Hill, NC, USA; E-mail: veronicakonjara@gmail.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

Floaters: Described as opacities with varying shapes that move with eye movements, due to vitreous condensations, or the presence of a Weiss ring or blood from retinal vessels. Nearly 70% of the patients who reported PVD with a concomitant hemorrhage had at least one break.

These kind of symptoms are all suggestive of retinal breaks. Evaluation should include examination with a corneal contact lens (Goldmann three mirror lens) or slit-lamp indirect biomicroscopy utilizing a 78 or 90 diopter lens. The vitreous cavity may be fully evaluated for the presence of cells by focusing at progressive depths in all quadrants. Careful search should be made for a vitreous face separated from the retinal surface, particularly in the posterior pole of the cavity, and the possible presence of a Weiss ring (Fig. **1**). Peripheral retinal examination should be done with indirect ophthalmoscope and scleral depression. If vitreous hemorrhage precludes adequate retinal examination, B-scan ultrasonography is advisable [4].

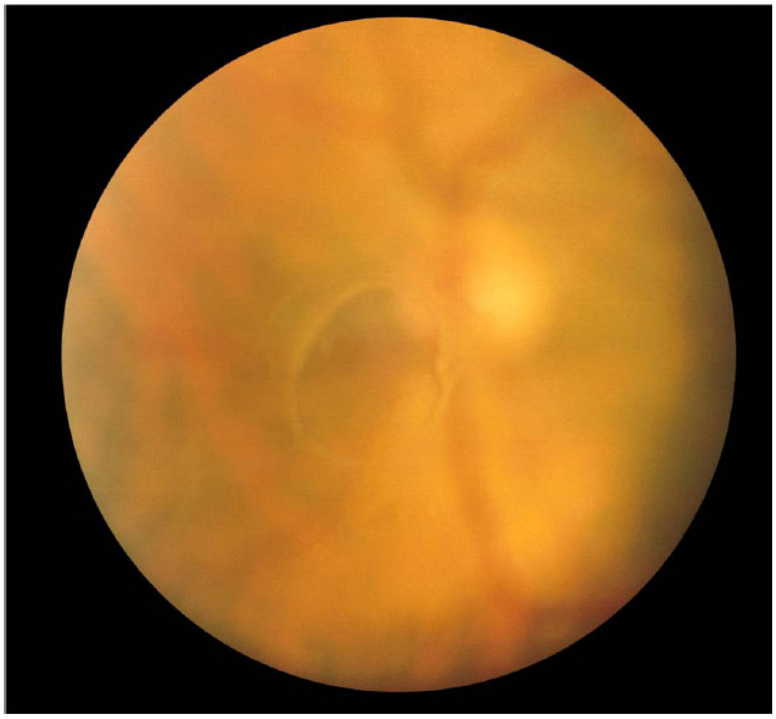

Fig. (1). Posterior vitreous detachment with Weiss ring (Courtesy of Jorge Bar MD, Argentina).

Almost 20% of the patients with symptoms have a retinal break at the moment of examination and there is a direct correlation between the amount of vitreous hemorrhage and the likelihood of a retinal tear [5]. If no retinal breaks are present, but there is vitreous or retinal hemorrhage, a new examination must be considered in the following 3-4 weeks due to a 5% chance of a retinal break. The annual incidence of RRD is approximately 10 to 15 per 100,000 persons [6, 7]. Of these cases, approximately 20% have had cataract surgery and 10% have had ocular trauma [8, 9]. Other risk factors for RRD are myopia and lattice degeneration [3]. Around 80% of eyes that have no breaks at the initial visit, but develop a retinal break during the following weeks, have either a hemorrhage in the vitreous or retina, or new symptoms that required a new evaluation [10].

Classification

PVD may be classified in four stages based on optical coherence tomography or ultrasound imaging using a 10 MHz probe straight to the fovea (Table **1**).

Table 1. Stages of posterior vitreous detachment [3].

Stage 1	Perifoveal separation with adhesion of vitreous to the fovea.
Stage 2	Complete separation of vitreous from the macula.
Stage 3	Extensive vitreous separation with adhesion of vitreous to the disc.
Stage 4	Complete posterior vitreous detachment.

MANAGEMENT

PVD without symptoms: Patient education regarding symptoms of vitreous traction, hemorrhage and retinal detachment. Re-examination annually.

PVD with symptoms (flashes/floaters): Reassurance. Patient education regarding change in nature of symptoms suggesting progression. Re-examination in 4-6 weeks, then 3-4 months, then annually.

PVD with vitreous hemorrhage that precludes retinal examination: B-scan ultrasonography. Clinical examination and B-scan 1 week, then every 1-2 weeks for 6 weeks, then less frequently if no indication of retinal tear or detachment [4].

CHAPTER 9

Asteroid Hyalosis

Naty C. Torres Soriano[1,2] and **Mitzy E. Torres Soriano**[1,3,*]

[1] *Centro Médico Cagua, Unidad Oftalmológica "Dr. Torres López", Cagua-Aragua, Venezuela*

[2] *Ophthalmology Department, Hospital Central de Maracay, Maracay, Venezuela*

[3] *Centro de la Visión Gordon-Manavella, Rosario, Santa Fe, Argentina*

The asteroid hyalosis is a degenerative disease of the vitreous characterized by the presence of multiple birefringent yellowish-white, round particles essentially composed of calcium and phosphate dispersed in the vitreous [1,2]. Its incidence has been estimated at 0.5%. Usually it is unilateral (75%) and observed in patients over 60 years of age. It more commonly affects males than females (3/1) [2-4].

The origin of the asteroid hyalosis remains unknown, but current theories suggest that it is a result of the aging of collagen within the vitreous or depolymerization of hyaluronic acid. There may be a greater prevalence in patients with diabetes, systemic arterial hypertension, hypercholesterolemia, atherosclerotic vascular disease, and hyperopia [3-5].

ESSENTIALS OF DIAGNOSIS

The findings in this disease are very characteristic. It is usually asymptomatic; in severe cases it may slightly affect visual acuity. Floaters are rare.

The biomicroscopic examination is characterized by tiny corpuscles solid, spherical or discoid (white or yellow with little mobility) suspended in an essentially normal vitreous although it may be fibrillar vitreous degeneration. The asteroid bodies are arranged in columns or clusters but more often manifest in the random arrangement [3] (Figs. **1** and **2**).

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

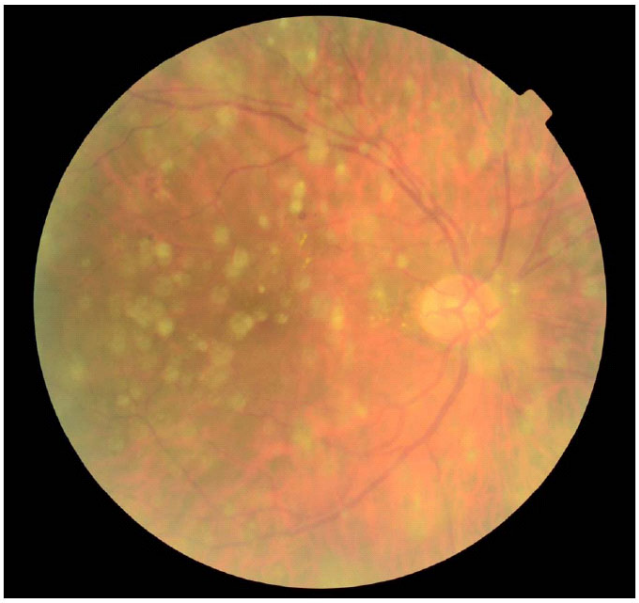

Fig. (1). Asteroid hyalosis: Small, dense, spherical white opacities, fixed in location, attached to vitreous fibrils in the random arrangement.

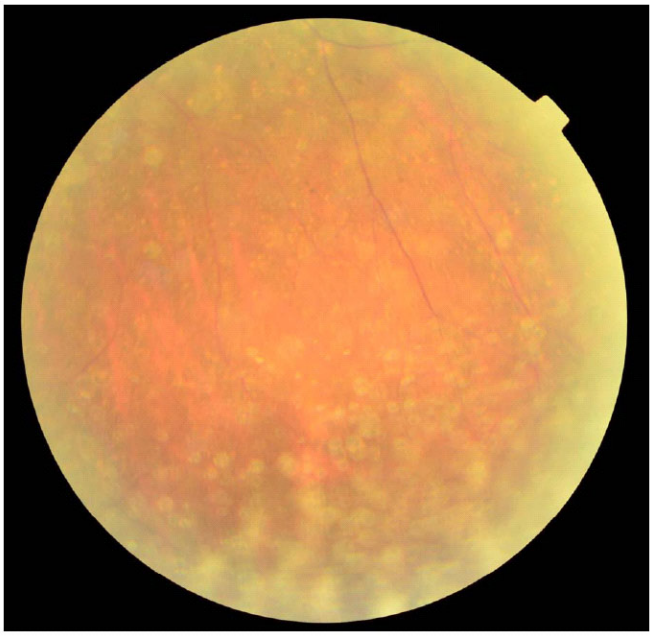

Fig. (2). Left eye of a 64 year-old female with hypertensive retinopathy, vascular occlusion, and asteroid hyalosis. Small white opacities in inferior portion of vitreous cavity.

The ophthalmoscopic examination is characterized by asteroid bodies that reflect light and give a picture as “stars shining in the night sky”. With eye movements have slight mobility but always returning to the original position [1, 3]. Because these opacities cast very short cones of shadow, the patient does not perceive them. They have minimal, if any, effect on vision but by reflecting light back to the observer, they may obscure visualization of the fundus, at times to a severe degree. The use of fluorescein angiography, optical coherence tomography, and ocular ultrasound in these situations may provide extra information about the retinal condition that might not be possible by ophthalmoscopy alone [5] (Fig. **3**).

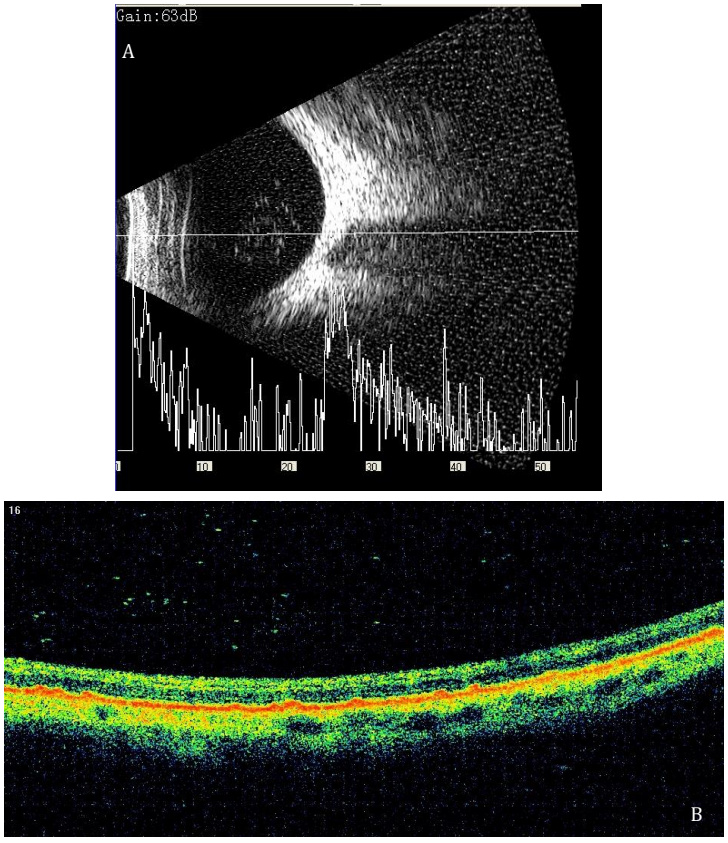

Fig. (3). Studies of the same patient of Fig. (**2**). (**A**). A contact A and B-scan showing hyperechoic dots in vitreous cavity. (**B**). OCT showing some hyperreflective points in the posterior vitreous and severe retinal atrophy.

CHAPTER 10

Vitreous Hemorrhage

Matko Vidosevich[1,*], **Carolina Merlo**[1] and **Gerardo Garcia-Aguirre**[2,3]

[1] *Microcirugía Ocular Rosario, Rosario-Santa Fe, Argentina*

[2] *Asociación para Evitar la Ceguera en Mexico, Mexico City, Mexico*

[3] *Escuela de Medicina del Tecnológico de Monterrey, Mexico City, Mexico*

Vitreous hemorrhage is defined as the presence of red blood cells within the vitreous cavity. It is a frequent cause of visual disturbance, and may be caused by a wide variety of vitreoretinal pathologies [1 - 6].

ESSENTIALS OF DIAGNOSIS

Patients complain of sudden and painless decrease of visual acuity, which is usually unilateral. The intensity of visual loss will depend on the amount of blood present in the vitreous cavity. The patient usually describes the presence of floaters.

Diagnosis is relatively straightforward during ophthalmologic examination, where blood is seen trapped in the vitreous fibers (Figs. **1**, **2**). If hemorrhage is recent, it will be bright red in appearance. If hemorrhage occurred 2-3 months before examination, it may turn yellowish. Fundus details may be obscured, depending on the amount of hemorrhage. In some eyes (especially when diabetic retinopathy is the underlying cause), hemorrhage may become trapped between the detached posterior hyaloid and the retina, causing a so-called subhyaloid hemorrhage (Fig. **3**).

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

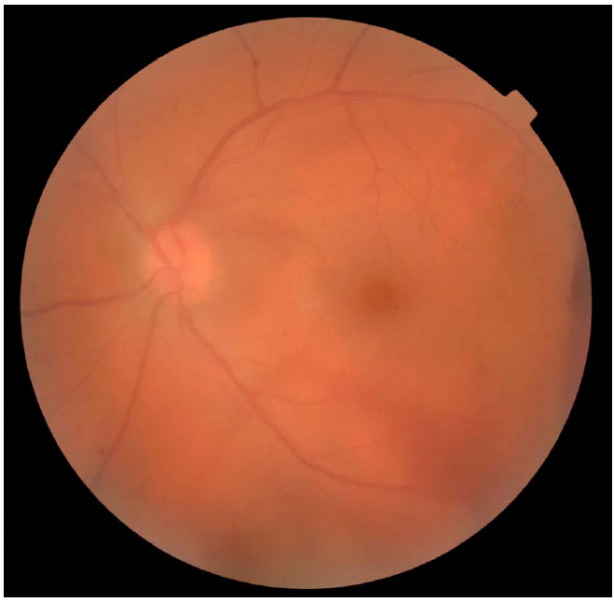

Fig. (1). Vítreous hemorrhage in patient with arterial hypertension (Courtesy of Manuel Torres López, Cagua - Venezuela).

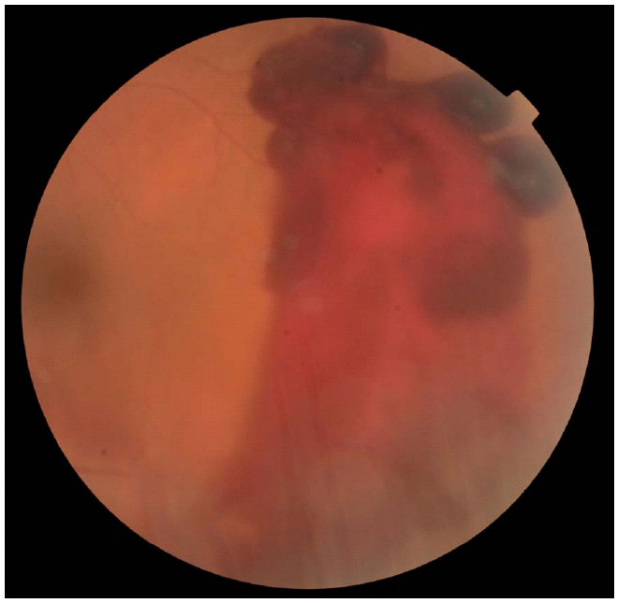

Fig. (2). Same patient as Fig. (**1**) Vítreous, subhyaloid and subretinal hemorrhage in temporal side, probably secondary to arterial macroaneurysm (Courtesy of Manuel Torres López, Cagua - Venezuela).

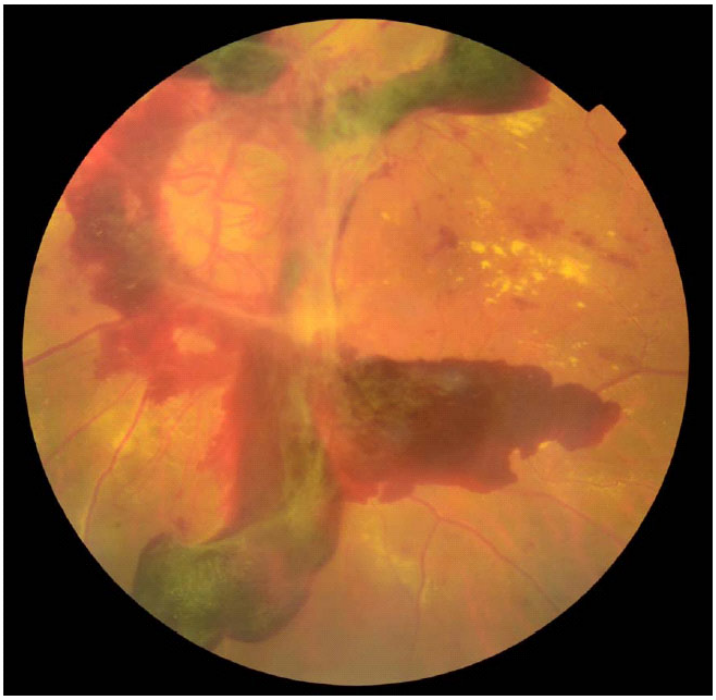

Fig. (3). Subhyaloid hemorrhage secondary to proliferative diabetic retinopathy. It reveals retinal hemorrhages, hard exudates and neovascularization (Courtesy of Manuel Torres López, Cagua - Venezuela).

If the amount of hemorrhage precludes visualization of the fundus, a B-scan ultrasonogram is needed to evaluate the retina and the choroid (Fig. **4**). Examination of the contralateral eye may give valuable clues regarding the etiology of the hemorrhage.

DIFFERENTIAL DIAGNOSIS

The most frequent causes of vitreous hemorrhage in adults are, in order of frequency: Acute posterior vitreous detachment, diabetic retinopathy, retinal vein occlusion, trauma, and breakthrough hemorrhage from a choroidal neovascularization. In children, diseases such as shaken baby syndrome, Coats' disease, pars planitis or familial exudative vitreoretinopathy should be ruled out.

Ophthalmologic examination should be sufficient to make the diagnosis. However, B-scan ultrasound and fluorescein angiogram are valuable tools to elucidate the etiology.

CHAPTER 11

Retinal Breaks and Peripheral Retinal Degenerations

Guillermo Iribarren[1,*] and **Mariano Iros**[2]

[1] *Opthalmology Service, Hospital Alemán, Buenos Aires, Argentina*

[2] *Clínica de Ojos Córdoba, Córdoba, Argentina*

These lesions are usually located between the equator and the ora serrata. They have the potential risk of developing retinal breaks and retinal detachment.

ESSENTIALS OF DIAGNOSIS

Diagnosis is made through fundus examination with slit lamp and contact lenses, indirect ophthalmoscopy with scleral indentation or wide field fundus imaging.

Retinal Breaks

These are full thickness holes in the retina. This allows liquefied vitreous to dissect the space between the neuroretina and the pigment epithelium. This produces an imbalance between the adhesion and traction forces that maintain the retina attached, and retinal detachment occurs. The vitreous has normal and abnormal attachments to the retina, some of them are not visible.

Aging of the vitreous include vitreous liquefaction and syneresis. Posterior vitreous detachment may be present in less than 10% of patients under 50 years old, but it increases to 27% of patients above 60 years old and 63% in patients over age 70 [1, 2] (Fig. **1**).

As the posterior vitreous detachment develops, traction is exerted on areas of vitreoretinal adhesion, and retinal breaks may develop [1, 2].

* **Corresponding author Guillermo Iribarren:** Ophthalmology Service, Hospital Alemán, Buenos Aires, Argentina; Tel: +54 (11) 43931844; E-mail: Iribarren.willy@gmail.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

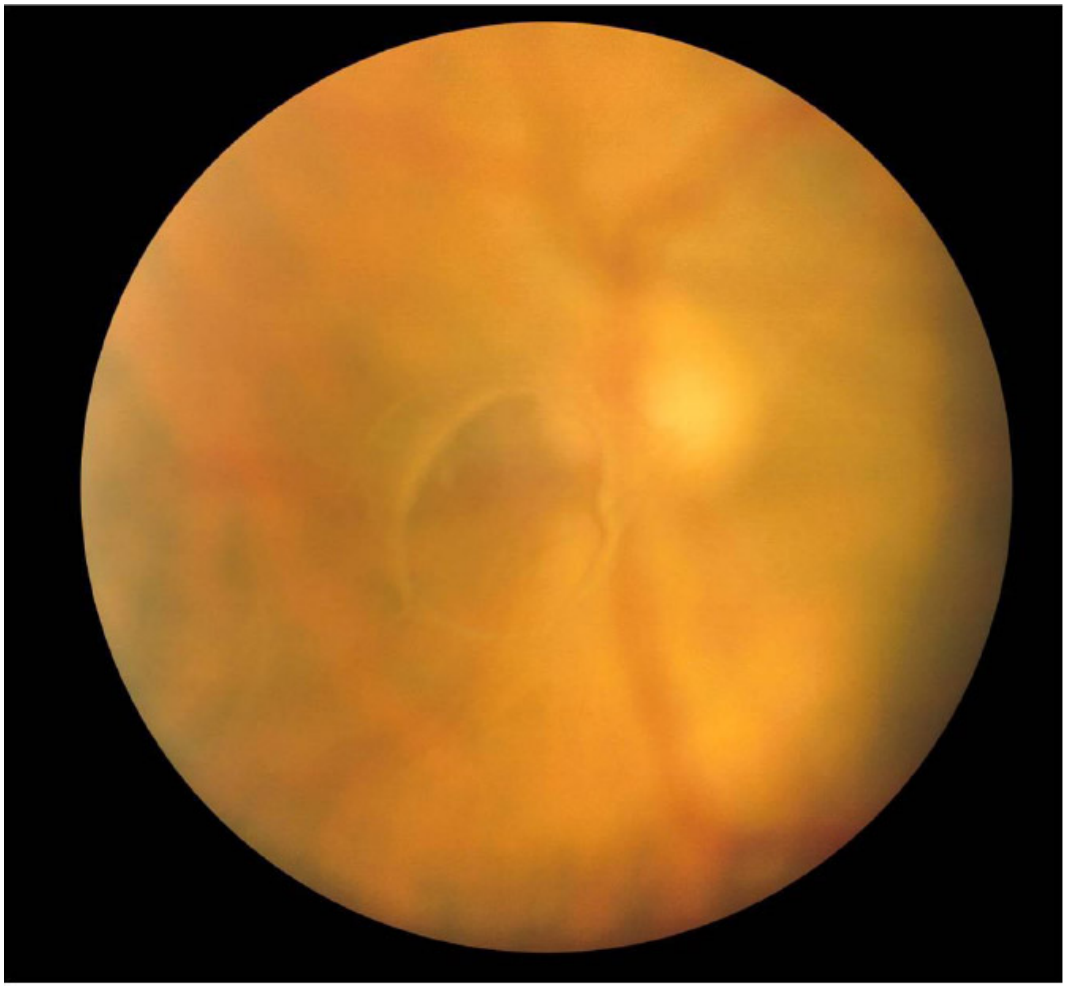

Fig. (1). Posterior vitreous detachment (Courtesy of Jorge Bar MD, Argentina).

The areas of especially firm vitreoretinal adhesion include several vitreoretinal degenerative disorders, meridional folds and complexes, tufts, oral bays, lattice degeneration, and perivascular vitreoretinal attachments. There are other sites of the retina that appear normal before retinal break formation.

Horseshoe Tears

They represent full thickness retinal breaks due to traction of the vitreous that remains attached to the retinal flap (Figs. **2 - 4**) [2].

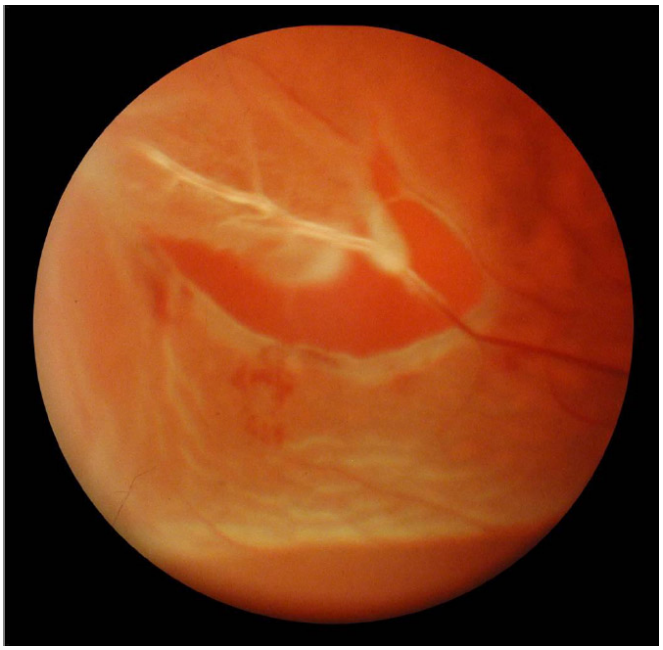

Fig. (2). Horseshoe tear and retinal detachment. Bridging of the overlying retinal vessel (Courtesy of Jorge Bar MD, Argentina).

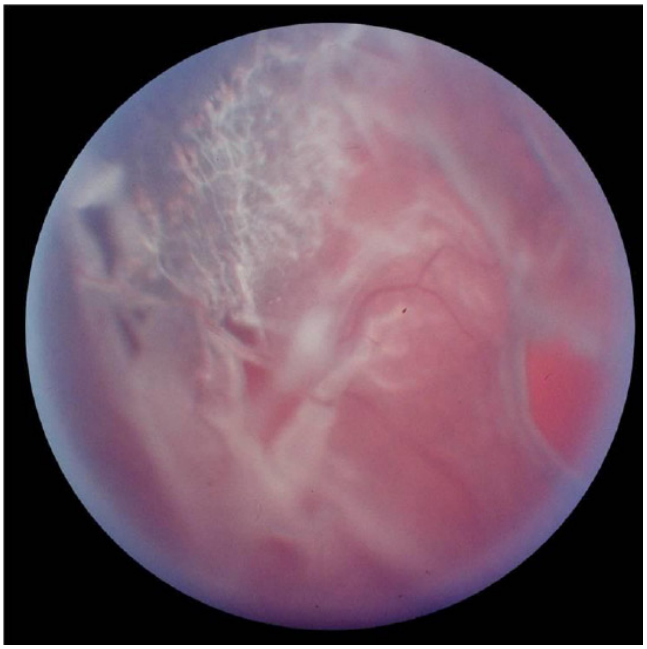

Fig. (3). Horseshoe tear and retinal detachment (Courtesy of Jorge Bar MD, Argentina).

CHAPTER 12

Rhegmatogenous Retinal Detachment

Paul Tornambe[1] and **Gerardo García-Aguirre**[2,3,*]

[1] *Retina Consultants of San Diego, Poway, CA, USA*

[2] *Asociación para Evitar la Ceguera en Mexico, Mexico City, Mexico*

[3] *Escuela de Medicina del Tecnológico de Monterrey, Mexico City, Mexico*

Rhegmatogenous retinal detachment (RRD) is defined as the separation of the neurosensory retina from the retinal pigment epithelium (RPE), secondary to passage of liquefied vitreous through one or more retinal breaks. These breaks usually originate either from vitreoretinal traction [1] or retinal atrophy [2], and when the amount of fluid entering the subretinal space through these breaks exceeds the amount that can be absorbed by the RPE, the retina becomes detached. It has an estimated incidence in the general population of 1 in 10,000, but the risk is increased in eyes with high myopia (over 6 diopters) or previous cataract surgery [2, 3].

ESSENTIALS OF DIAGNOSIS

Patients usually complain of vitreous floaters (which may correspond to vitreous hemorrhage secondary to a ruptured retinal blood vessel, or vitreous condensations that accompany posterior vitreous detachment) (Fig. **1**), photopsia (due to vitreoretinal traction) and/or a peripheral scotoma (when the retina is detaching).

Diagnosis of RRD is most of the time performed at the clinic. Clinical examination in early stages may reveal predisposing lesions in the periphery, which may take different shapes, such as lattice degeneration (Figs. **2** and **3**) [4], operculated hole (Figs. **3 - 5**) or a horseshoe retinal tear (Fig. **6**). In later stages

* **Corresponding author Gerardo García-Aguirre:** Vicente García Torres 46, San Lucas Coyoacan, Mexico City, Mexico, 04030; Tel +52 (55) 10841400; E-mail: jerry_gar_md@yahoo.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

localized subretinal fluid may be observed, which continues to extend and affect wider areas of the retina, which may take different configurations depending on the size and location of the lesion (Figs. **7 - 9**) [5]. Vitreous cells may be observed, either pigment cells know as "tobacco dust" or erythrocytes. If large areas of the retina are detached, the eye may become hypotonous. Chronic retinal detachments might be accompanied by proliferative vitreoretinopathy (Fig. **10**) or pigmentation demarcating the detachment area (Fig. **11**).

Fig. (2). Ultrawide field fundus photograph of the right eye showing lattice degeneration in the superotemporal periphery.

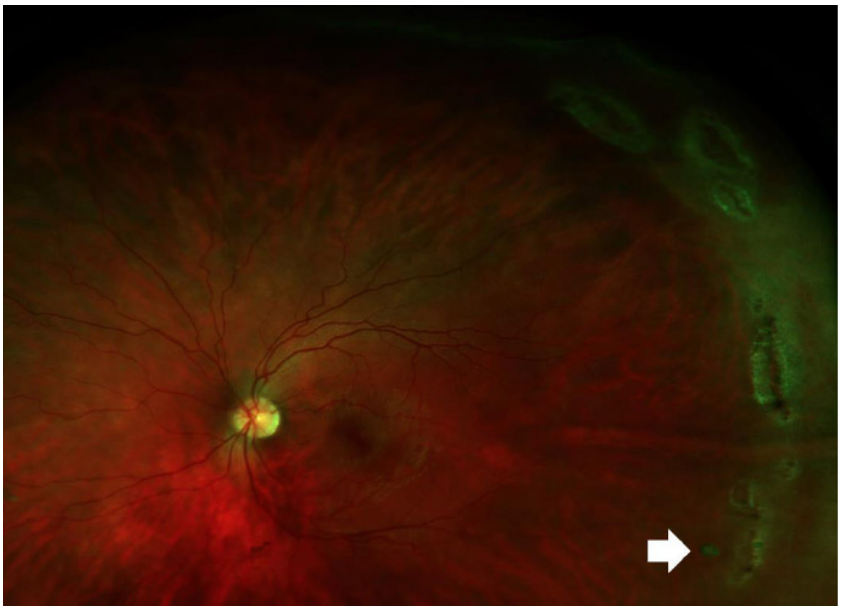

Fig. (3). Ultrawide field fundus photograph of a left eye, showing lattice degeneration in the temporal periphery, and a retinal hole with an associated operculum (arrow).

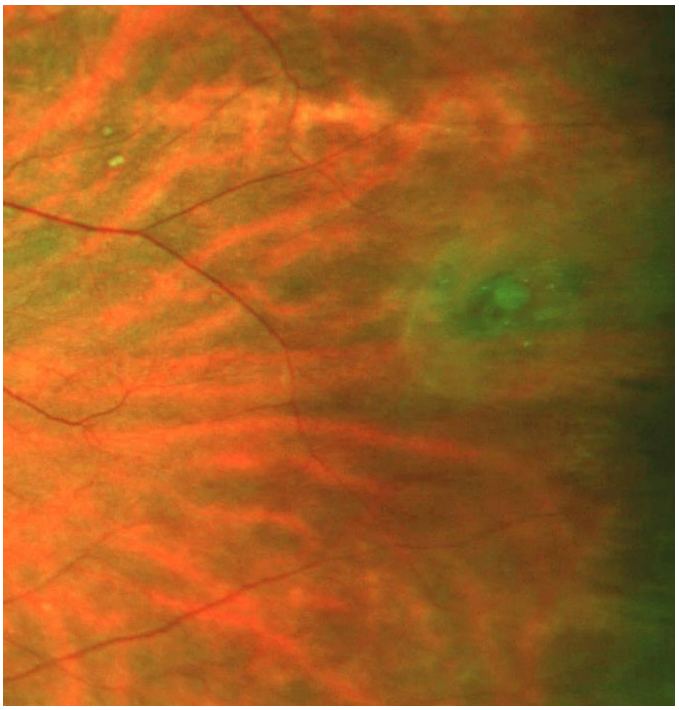

Fig. (4). Operculated retinal hole, with scarce subretinal fluid.

CHAPTER 13

Proliferative Vitreoretinopathy

Gastón Gómez Caride[1] and **Marcelo Zas**[2,*]

[1] *Retina Department, Centro de Ojos Quilmes, Provincia de Buenos Aires, Argentina*

[2] *Ophthalmology Department, Hospital de Clinicas " José de San Martín", School of Medicine, University of Buenos Aires, Argentina*

The retinal tear occurs without having an anatomical support that enables autofill the solution of continuity. Therefore, the retinal tear gives rise to the repair process producing a cell growth of the retinal pigment epithelium, glia or other cell types [1]. These cell types migrate over the internal and external surface of the retina and the anterior segment of the vitreous producing membranes called proliferative vitreoretinopathy (PVR).

ESSENTIALS OF DIAGNOSIS

PVR is the most frequent cause for lack of repair of the retinal detachment (around 10%). The PVR is an amplified healing process. Today there are multiple lines of research to elucidate the process and improve outcomes techniques.

The contraction of these membranes produces fixed retinal folds, equatorial traction, non-pigmented retinal detachment of the pars plana, and widespread retinal contraction.

Although some treatments such as low molecular weight heparin, cytostatics, and corticosteroids are used aiming to reduce the impact of PVR, their results do not change the incidence rate. As a consequence, the causal retinal ruptures may re-open, triggering new ruptures or a tractional retinal detachment.

* **Corresponding author Marcelo Zas:** Retina Department, Hospital de Clínicas “José de San Martín”, University of Buenos Aires, Buenos Aires, Argentina; Tel/Fax: +5411-44832-1849; E-mail: marcezas@gmail.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

The risk factors [2] are:

- Long time between the retinal detachment diagnosis and its surgical repair.
- Hemorrhage in the vitreous due to the rupture of retinal vessels.
- Giant tears.
- Multiple surgeries.
- Ocular damage mainly punctures.
- Young patients.
- Aphakia.
- Uveitis.
- Choroidal detachments.
- Excessive cryocoagulation.
- Postsurgical infection and inflammation.

PVR Classification

Grade A: Represents the presence of pigment in the vitreous space and on the surface of the retina (Fig. **1**).

Grade B: Fine folds on the surface of the retina. Proliferation in the vitreous tissue causes reduced retinal mobility in the vitreous cavity (Figs. **2** and **4**).

Grade C: Fixed retinal folds. They can be in the posterior or anterior segment, with an imaginary boundary in the equatorial part of the eyeball (PC – AC) (PC = posterior chamber; AC = anterior chamber) (Fig. **3**).

It is divided into 5 different degrees of contraction:

C1, Posterior focal star folds (Figs. **3a** and **5**).

C2, Posterior confluent irregular folds. Poor visualization of the optic disc (Figs. **3b** and **6**).

C3, Anterior and posterior subretinal annular strand close to the disc; linear strands with or without pigmentation; sheets with a moth-eaten appearance (Fig. **3c**).

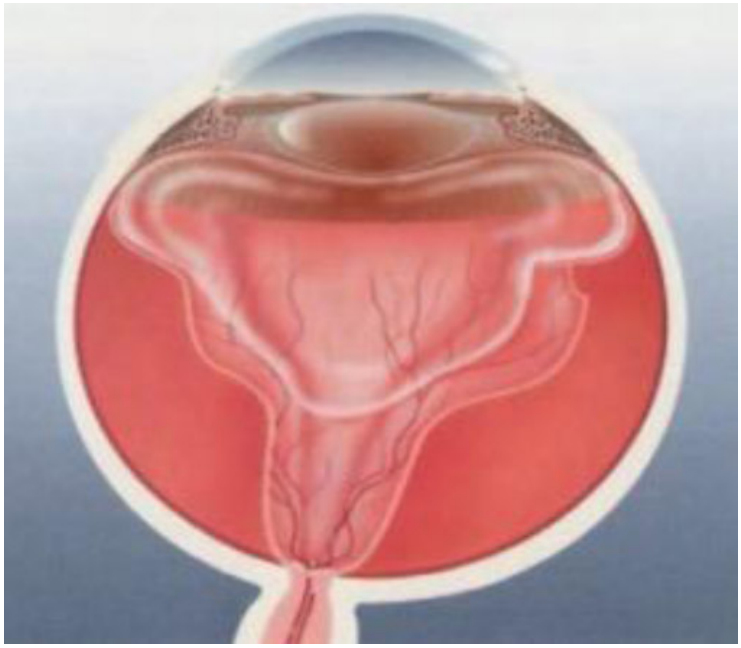

Fig. (1). PVR grade A.

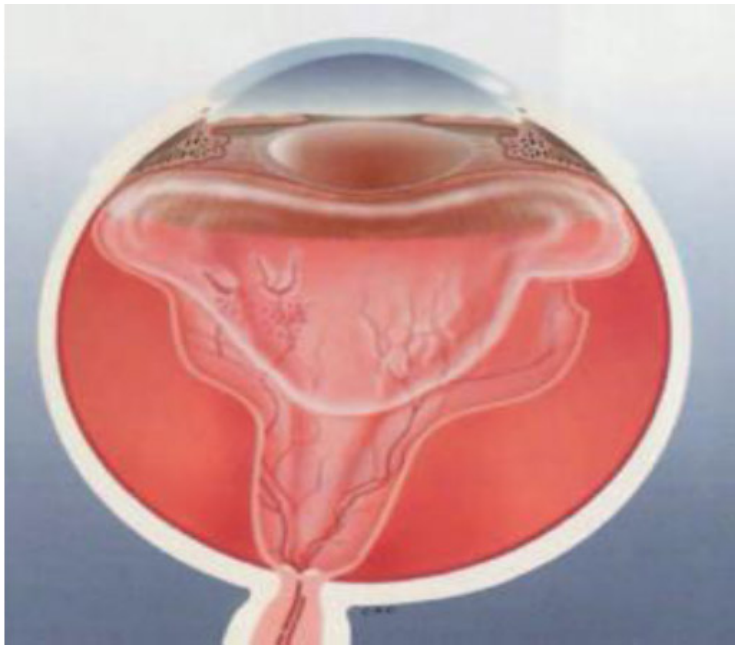

Fig. (2). PVR grade B.

CHAPTER 14

Retinopathy of Prematurity

Andrea Arriola-López, Miroslava Meraz-Gutiérrez and **María Ana Martínez-Castellanos***

Asociación para Evitar Ceguera en México, Hospital Luis Sanchez Bulnes IAP, Mexico City, Mexico

Retinopathy of prematurity (ROP) is a vasoproliferative disorder of the developing retina. It is one of the main causes of childhood blindness in developing countries [1]. Although prematurity and low birth weight are the greatest risk factors for developing ROP, there are a multitude of factors that have been implicated in the disease progression.

ESSENTIALS OF DIAGNOSIS

The International Classification of Retinopathy of Prematurity (ICROP) was developed to describe the early levels of severity of ROP based on zone, stage, extent of stage and presence of plus disease [1, 2].

The **zone** of ROP refers to I-III regions that describes the affected retinal area (Figs. **1 - 3**).

The **stage** of ROP defines the clinical appearance of the retina and the avascular area. There are 5 stages. In stage 1, a demarcation line is apparent (Fig. **4**). In stage 2, there is a prominent ridge and some vitreous traction (Fig. **5**). In stage 3 ROP, there is neovascularization growing onto the vitreous ridge (Fig. **6**). In stage 4, contraction of the fibrovascular proliferation causes traction on the retina leading to a partial retinal detachment, 4A without macular involvement and 4B with macular involvement (Fig. **7**). Stage 5 ROP is a total retinal detachment and is described as closed funnel when the retina is adherent to itself or open when

* **Corresponding author María Ana Martínez-Castellanos:** Asociación para Evitar Ceguera en México, Hospital Luis Sanchez Bulnes IAP, Mexico City, Mexico; Tel/Fax: +52 (55) 31263316; E-mail: mariamtzc@me.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

it is not (Fig. **8**). There is an anterior displacement of iris-lens diaphragm because of the retinal detachment and contraction of anterior vitreous fibers [3 - 5] (Fig. **9**).

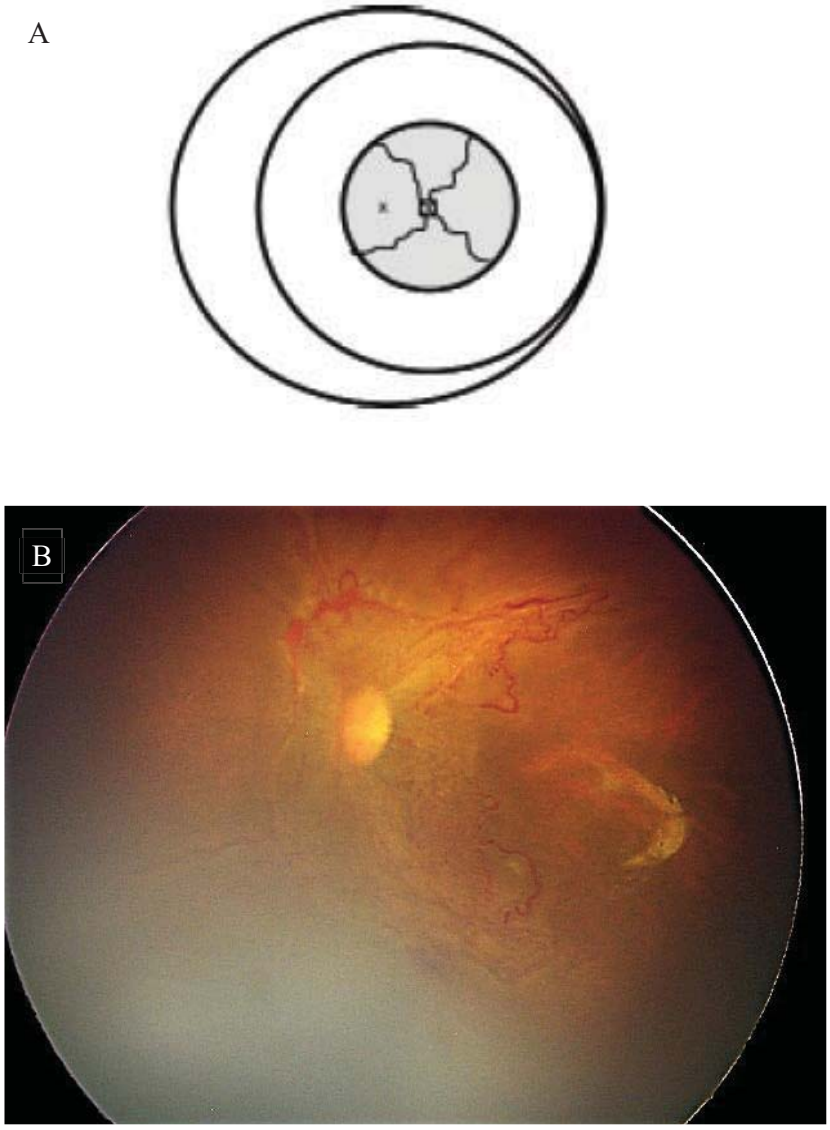

Fig. (1). (**A**). Diagram illustrating zone I, defined as a circle, the center of which is the disc, and the radius of which is twice the distance of the disc to the fovea. (**B**). Clinical photograph of a patient with zone I involvement.

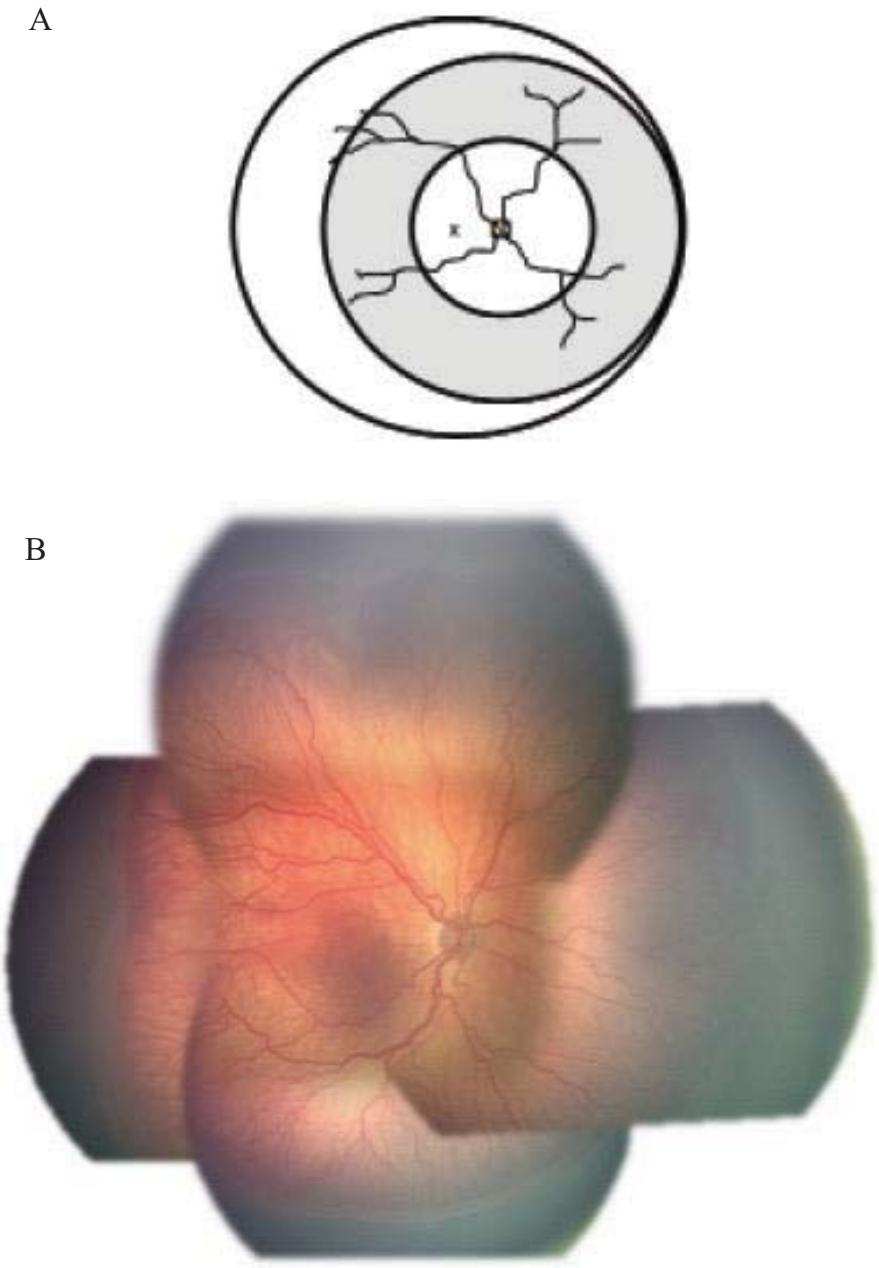

Fig. (2). (**A**). Diagram describing zone 2, which extends from the anterior border of zone I to within one disc-diameter of the ora serrata nasally and to the anatomic equator temporally. (**B**). Photograph composition of a patient that shows zone II involvement.

CHAPTER 15

Coats` Disease

Gabriel Ruíz Fernández*

OftalmoClínica, Ciudad de Santa Fe, Santa Fe, Argentina

Coats' disease is a retinal disease of unknown etiology, described by George Coats in 1908 [1] that is characterized by the presence of telangiectasias in the retinal vasculature that cause significant exudation [2].

Although the pathophysiology is unknown, a gene named NDP that codes for a protein known as norrin has been implicated in this and other diseases that involve retinal vasculogenesis [3]. Although syndromes such as Hallerman Streif or Senior Loken have been associated to Coats' disease, most patients present just with the retinal findings without a systemic association [4, 5].

Histologically, retinal vessels of eyes with Coats' disease have a significant reduction in the number of pericytes, which in turn leads to the vascular malformations and abnormal vascular permeability that are characteristic of this disease [6, 7].

ESSENTIALS OF DIAGNOSIS

Patients with Coats' disease present during the late first or early second decades of life [1], although there is an adult form of the disease [8, 9]. Around three quarters of patients are male, and in most of them, only one eye is affected [1].

Expression of the disease is variable: some patients may have very mild exudation and therefore be asymptomatic, while other patients with more significant exudation may present with leukocoria, strabismus or decreased visual acuity [10]. In adults, strabismus is less frequent as a presenting symptom [11].

* **Corresponding author Gabriel Ruíz Fernández:** OftalmoClínica, 25 de Mayo 2980, Ciudad de Santa Fe, Santa Fe, Argentina; Tel: +54 (342) 452-2247; E-mail: gabrielruizfernandez@hotmail.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

Fundus examination of an eye with Coats' disease usually shows a significant amount of subretinal yellow exudates (Fig. **1**) that is associated to vascular malformations such as aneurysms or telangiectasias that are located in the retinal periphery and affect mainly the temporal retina.

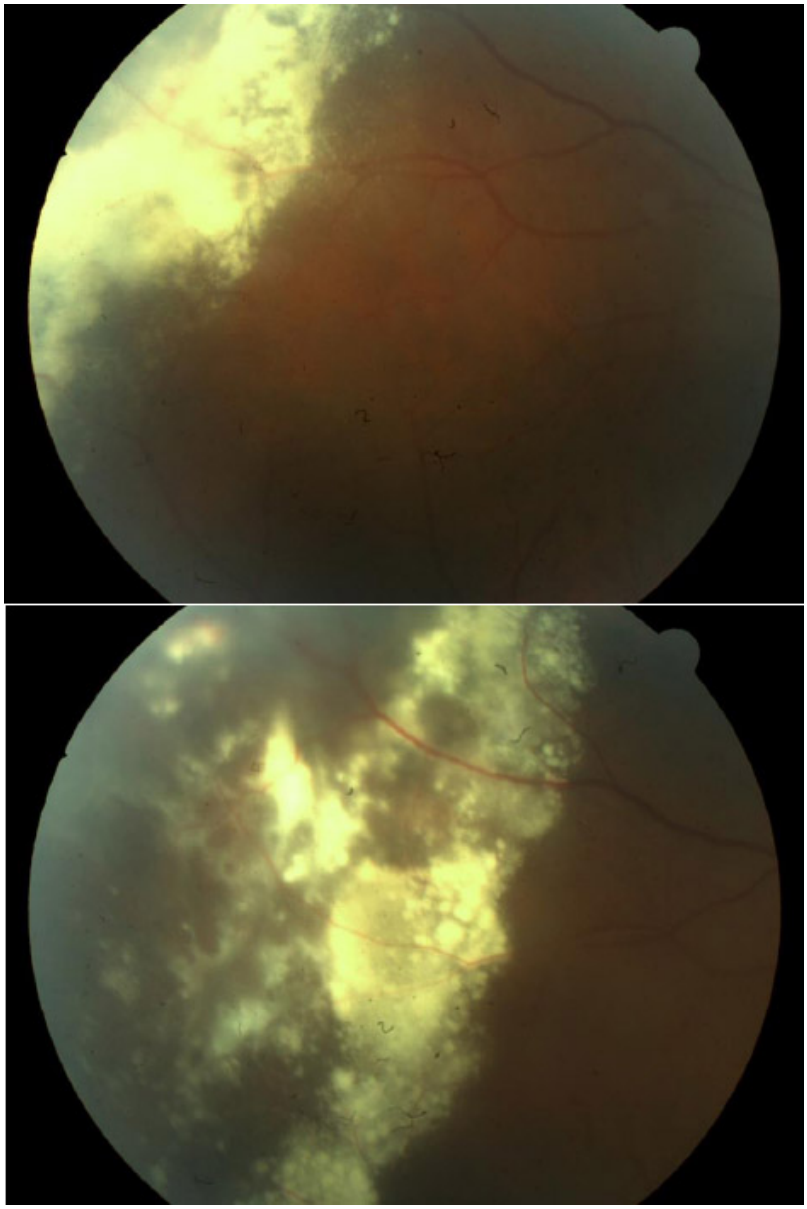

Fig. (1). Fundus photograph of 55-year-old man with Coats' disease. It shows peripheral exudation.

Clinical course of the disease may be variable but is generally progressive. Acute exacerbations of the disease may be separate in time by more quiescent stages [11]. Spontaneous remission has been reported but is really uncommon [12]. Subretinal exudation tends to increase in time, causing a serous retinal detachment that may progress until the affected retina becomes visible behind the lens. Eventually, neovascular glaucoma may develop and lead to phthisis bulbi in severe cases [11].

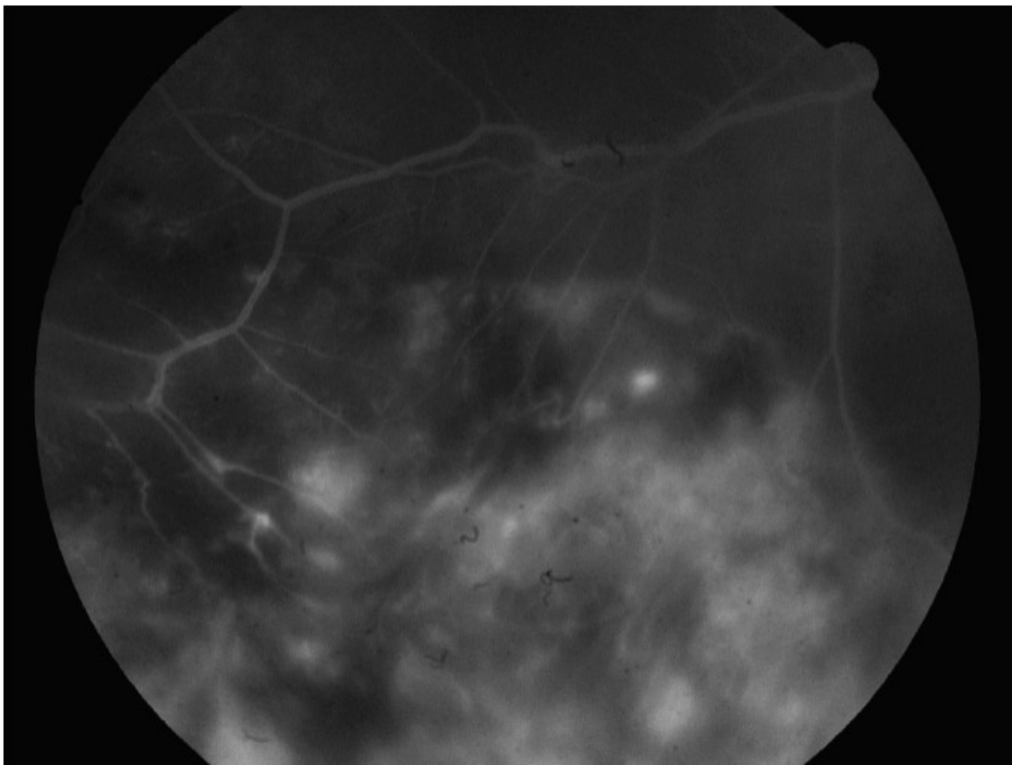

Fig. (2). Fluorescein angiogram of the same patient of Fig. (**1**) reveals several areas of hyperfluorescence from leaking retinal telangiectasia, giving a typical 'light bulb' appearance.

Fluorescein angiography shows retinal telangiectasia giving a typical "light bulb appearance", aneurysms, beading of vessels walls, and arteriovenous shunts are seen in the larger vessels involved (Fig. **2**). These vessels show early and persistent leakage. Areas of capillary non-perfusion or macular edema may appear [11]. Optical coherence tomography [13], is a very valuable tool to monitor response to treatment, especially in the macular area [13 - 15]. In advanced cases

CHAPTER 16

Ocular Toxocariasis

García A. Reinaldo[1,*], J. Fernando Arevalo[2,3], Rafael Muci Mendoza[4], Verónica Oria[1] and **Luis Suarez Tata[1]**

[1] *Clínica Oftalmológica El Viñedo, Valencia, Venezuela*

[2] *The Retina Division, Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD, USA*

[3] *The King Khaled Eye Specialist Hospital, Riyadh, Kingdom of Saudi Arabia*

[4] *The Neurophthalmology Unit "Dr. Rafael Muci Mendoza" Hospital J. M. Vargas, Caracas, Venezuela*

Toxocariasis is a very frequent helminthic infection, caused by the larval stages of the ascarids *Toxocara canis* and *catis*, the common roundworm of dogs and cats respectively. Egg and larval forms of *Toxocara* have difficulty surviving at temperatures below 50°F (10°C), which is why the disease is more prevalent in warmer climates [1]. Playgrounds and sandboxes are common sources of contamination because they are regularly frequented by dogs, cats and children (higher risk population) who ingest dirt because of their play habits and hygiene standards [1 - 4] (Fig. **1**).

Toxocara infection in humans originates with ingestion of infectious *Toxocara* eggs, and can have three distinct clinical pictures: visceral larva migrans, ocular larva migrans, and covert toxocariasis. Visceral larva migrans occurs when *Toxocara* larvae reach major internal organs through the bloodstream, causing a variety of symptoms, such as eosinophilia, headache, abdominal pain, pneumonitis, or hepatitis. Ocular larva migrans occurs when larvae migrate into the eye [3 - 5] (Fig. **2**). Contrary to visceral larva migrans, patients with ocular affection do not develop eosinophilia, leukocytosis and have normal serum IgE

[*] **Corresponding author Reinaldo García A.:** Clínica Oftalmológica El Viñedo, Valencia, Venezuela; Tel: +58-212-9774708; E-mail: reinaldogarcia2003@yahoo.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

levels [3 - 6]. Covert toxocariasis, on the other hand, represents a diagnostic challenge since symptoms are nonspecific (coughing, wheezing) accompanied by eosinophilia [3 - 6].

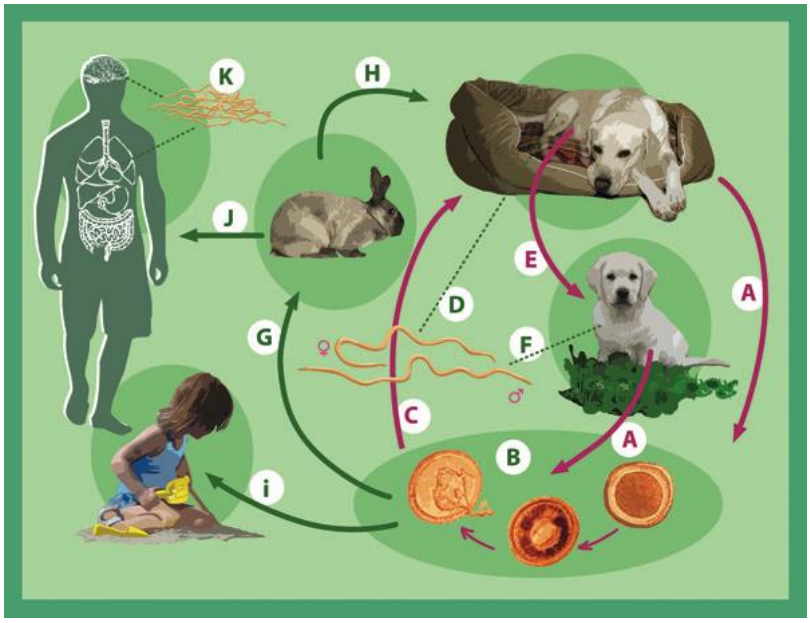

Fig. (1). *Toxocara* life cycle. (**A**) *Toxocara canis* accomplishes its life cycle in dogs, with humans acquiring the infection as accidental hosts. (**B**) Unembryonated eggs are shed in the feces of the definitive host. Eggs embryonate and become infective in the environment. (**C-D**) Following ingestion by dogs, the infective eggs hatch and larvae penetrate the gut wall. In younger dogs, the larvae migrate through the lungs, bronchial tree, and esophagus; adult worms develop and oviposit in the small intestine. (**E-F**) In older dogs, patent infections can also occur, but larval encystment in tissues is more common. Encysted stages are reactivated in female dogs during late pregnancy and infect by the transplacental and transmammary routes the puppies, in whose small intestine adult worms become established. Puppies are a major source of environmental egg contamination. (**G**) *Toxocara canis* can also be transmitted through ingestion of paratenic hosts: eggs ingested by small mammals (*e.g.* rabbits) hatch and larvae penetrate the gut wall and migrate into various tissues where they encyst. (**H**) The life cycle is completed when dogs eat these hosts and the larvae develop into egg-laying adult worms in the small intestine. (**I-J**) Humans are accidental hosts who become infected by ingesting infective eggs in contaminated soil or infected paratenic hosts. (**K**) After ingestion, the eggs hatch and larvae penetrate the intestinal wall and are carried by the circulation to a wide variety of tissues (liver, heart, lungs, brain, muscle, eyes). While the larvae do not undergo any further development in these sites, they can cause severe local reactions that are the basis of toxocariasis. The two main clinical presentations of toxocariasis are visceral larva migrans and ocular larva migrans. Diagnosis is usually made by serology or the finding of larvae in biopsy or autopsy specimens. CHAPTER 17

Familial Exudative Vitreoretinopathy

Yoshihiro Yonekawa[1], Antonio Capone[2] and **R.V. Paul Chan[3,*]**

[1] *Massachusetts Eye and Ear Infirmary and Boston Children's Hospital, Harvard Medical School, Boston, MA, USA Oakland University William Beaumont School of Medicine, Royal Oak, MI, USA*

[2] *Oakland University William Beaumont School of Medicine, Royal Oak, MI, USA*

[3] *Department of Ophthalmology, Illinois Eye and Ear Infirmary, University of Illinois at Chicago, Chicago, IL, USA*

Familial exudative vitreoretinopathy (FEVR) is a hereditary anomaly of retinal vascular development caused by *Wnt* signaling genetic defects [1].

ESSENTIALS OF DIAGNOSIS

The clinical presentation is highly variable, from subtle asymptomatic peripheral vascular changes to dragging of retinal vessels and severe tractional retinal detachments [2, 3]. Widefield fluorescein angiography with imaging systems such as the RetCam (Clarity Medical Systems, Pleansanton, CA, USA) for younger children and Optos (Optos, Marlborough, MA, USA) for older children and adults, greatly enhance the ability to diagnose and manage patients with FEVR.

FEVR staging is based on clinical and angiographic findings [4]. Stage 1 FEVR is characterized by peripheral nonperfusion with abnormally pruned distal retinal vasculature, such as bulb-like endings, telangiectatic vessels, supernumerary branching, and circumferential vascular loops (Fig. **1**). Extraretinal neovascularization characterizes stage 2, usually observed at the junction of vascular and avascular retina (Fig. **2**). Stage 3 and 4 are macula-sparing and macula-involving tractional retinal detachment, respectively (Fig. **3**). Total retinal detachment is

* **Corresponding author R.V. Paul Chan:** Pediatric Retina and Retinopathy of Prematurity Service, Illinois Eye and Ear Infirmary, University of Illinois at Chicago, 1855 W. Taylor St, Chicago, IL, USA 60612; Tel: (312) 413-1783; Fax: (312) 996-7770; E-mail: rvpchan@uic.edu

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

denoted as stage 5, which can have open or closed funnel configurations.

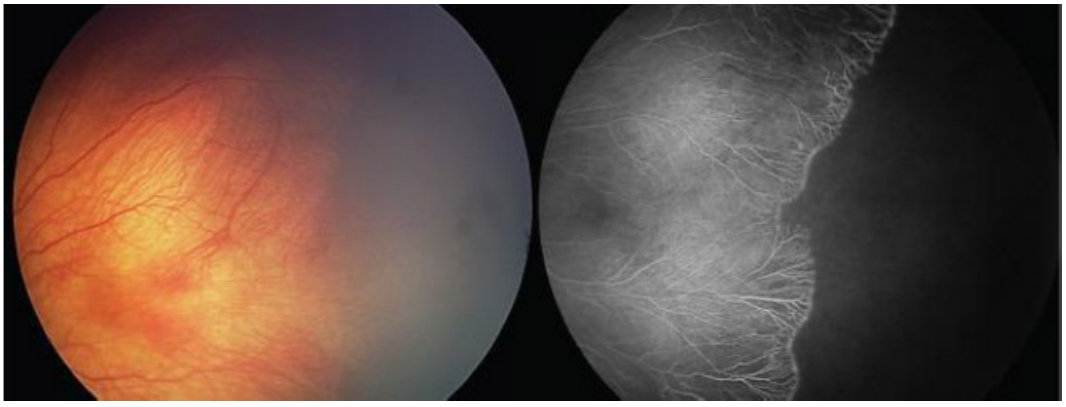

Fig. (1). Stage 1 Familial exudative vitreoretinopathy (FEVR). Stage 1 FEVR is characterized by peripheral nonperfusion with abnormal vascular endings. In this example, the clinical examination shows that there is peripheral nonperfusion (left), and RetCam widefield fluorescein angiography reveals that there is supernumerary branching and pruning of the vascular tips with extensive distal nonperfusion (right).

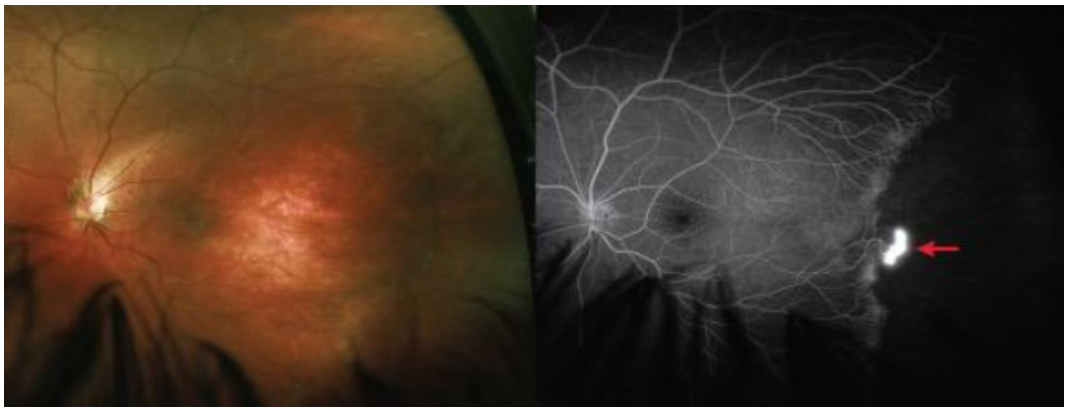

Fig. (2). Stage 2 Familial exudative vitreoretinopathy (FEVR). Stage 2 FEVR is characterized by retinal neovascularization, which is seen at the junction between vascular and avascular retina. Optos widefield fluorescein angiography in this example (right) shows a frond of retinal neovascularization seen as intense focal leakage of dye. Also note the abnormal vascular endings and the distal nonperfusion.

Diagnostic pearls for FEVR in order to distinguish it from other pediatric vitreoretinopathies are: (1) Careful inspection of the fellow eye. FEVR typically has bilateral findings, and identifying peripheral vascular changes in the less involved eye can help secure a diagnosis. (2) Examining family members for findings suggestive of FEVR – the majority of asymptomatic family members will

have clinical or angiographic findings [5]. (3) Genetic testing for mutations in *FZD4*, *NDP*, *TSPAN12*, and *LRP5*, are confirmatory. Although approximately only half of patients with FEVR will have detectable mutations, it is helpful when the clinical presentation is not typical [5].

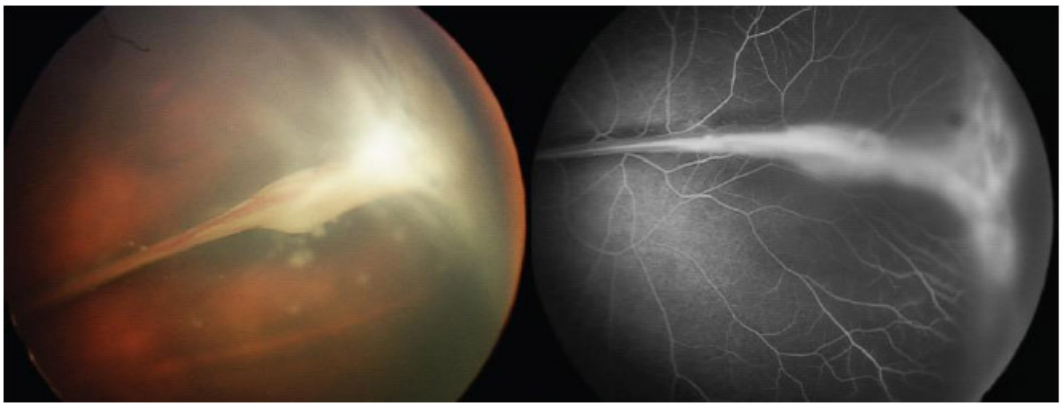

Fig. (3). Stage 4 Familial exudative vitreoretinopathy (FEVR). Macula-sparing tractional retinal detachment is considered stage 3 FEVR, macular-involving is stage 4, and total detachment is stage 5. In this example, there is a radial retinal fold involving the macula (stage 4), which is pulled up to the posterior lens surface.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of FEVR depends on the stage of disease [6, 7]. Several pediatric retinopathies may mimic stages 1-2. Retinopathy of prematurity (ROP) that spontaneously regressed or treated with anti-VEGF agents may present with similar peripheral vascular findings. Inquiring about birth history is therefore important for all suspected FEVR patients. In addition, ridges of previous arterial-venous shunting will often characterize regressed ROP, which is not seen in FEVR. Incontinentia pigmenti (IP) can usually be differentiated by the characteristic dermatologic findings and X-linked dominant inheritance pattern. The vascular anomalies in Coats' disease tend to be more sectorial with prominence of telangiectasias, bulb-like capillary endings, and extensive exudation. Of note, Coats' disease is not a vitreoretinopathy; hyaloid contraction will not be seen in Coats,' but it is a key element in FEVR, especially in advanced disease. Sickle cell retinopathy, Eales' disease, and diabetic retinopathy should also be considered, depending on the demographics and medical history.

CHAPTER 18

Persistent Fetal Vasculature

Yoshihiro Yonekawa[1], Antonio Capone Jr.[1] and **R.V. Paul Chan[2,*]**

[1] *Oakland University William Beaumont School of Medicine, Royal Oak, MI, USA*

[2] *Department of Ophthalmology, Illinois Eye and Ear Infirmary, University of Illinois at Chicago, Chicago, IL, USA*

Persistent fetal vasculature (PFV), also known as persistent hyperplastic primary vitreous, is a congenital developmental disorder of the hyaloid system. Hyaloid vasculature reaches peak prominence during the 8th to 12th weeks of gestation in the human embryo, after which it normally regresses gradually to establish a clear visual axis [1]. PFV occurs when the hyaloid system fails to regress, and the remnants of embryonic tissues cause varying degrees of pathology.

ESSENTIALS OF DIAGNOSIS

PFV is classically described in a smaller eye with elongated ciliary processes and a posterior lenticular opacity connected to a stalk emanating from the optic disc. However, the phenotypic spectrum is very broad: the mildest forms of PFV are the Mittendorf dot on the lens capsule and Bergmeister's papilla on the optic disc, while advanced forms present with dense leukocoria and underlying complex tractional retinal detachment (Figs. **1 - 3**).

An understanding of developmental anatomy facilitates accurate diagnosis [2]. There are two components to fetal vasculature: the tunica vasculosa lentis, and the hyaloid system (primary vitreous). Anteriorly, the tunica vasculosa lentis encompasses the lens and extends to the pupillary margins. Posteriorly, it envelops the

* **Corresponding author R.V. Paul Chan:** Pediatric Retina and Retinopathy of Prematurity Service, Illinois Eye and Ear Infirmary, University of Illinois at Chicago, 1855 W. Taylor St, Chicago, IL, USA 60612; Tel: (312) 413-1783; Fax: (312) 996-7770; E-mail: rvpchan@uic.edu

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

posterior surface of the lens and extends to the ciliary processes. The posterior tunica connects with the hyaloid vessel that emanates from the optic disc. It is important to remember that hyaloid vasculature is not just the central hyaloid vessel as commonly drawn in figures; depending on the patient, it can fill the entire vitreous cavity with multiple tractional attachments to the retina. There can be variable degrees of retinal dysplasia in PFV also, which can limit visual potential despite optimal management. The disease itself is usually not progressive, but as the eye grows, the traction will also increase, and hypotony from ciliary body traction may occur [3].

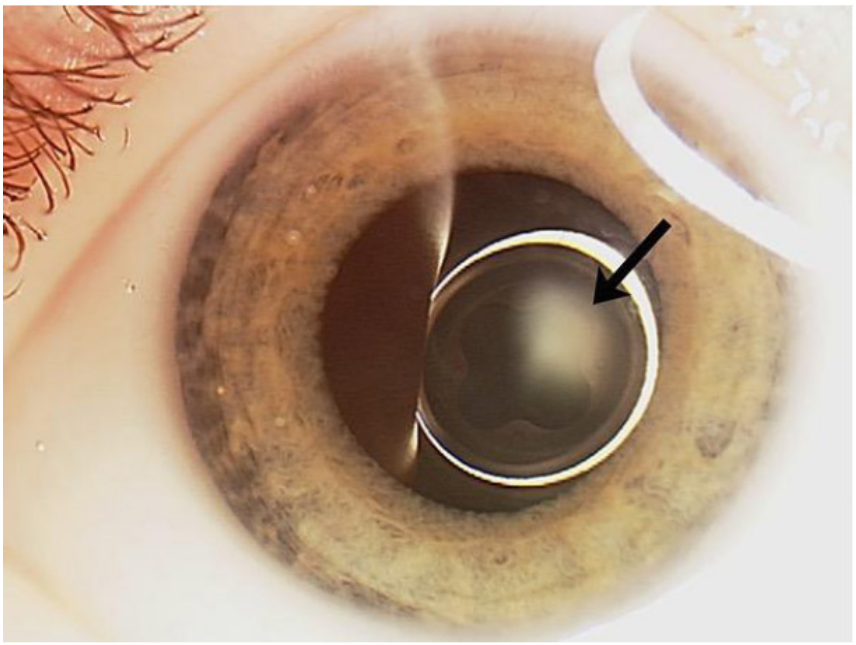

Fig. (1). Persistent fetal vasculature. This is an anterior segment photograph of a 6-month-old boy who presented with unilateral leukocoria. There is a white opacity attached to the posterior aspect of the crystalline lens (arrow).

A rare form of PFV is associated with posterior lenticonus and coloboma, a syndrome named microcornea, posterior megalolenticonus, PFV, and coloboma (MPPC) [4]. Like most syndromes, the presentation will vary and certain components of the syndrome will predominate the clinical picture. The megalolenticonus protrudes posteriorly, and the lens may even occupy the majority of the vitreous cavity.

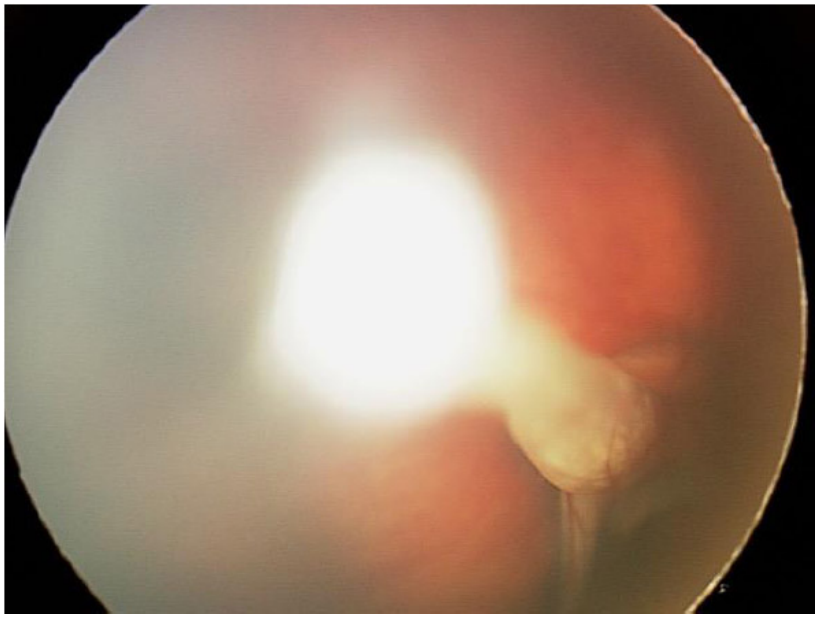

Fig. (2). Persistent fetal vasculature. A dilated fundus examination in the same patient as Fig. (**1**) showed a vascular stalk that was connected to the optic disc. Retinal tissue and vasculature are also pulled up and incorporated into the base of the stalk.

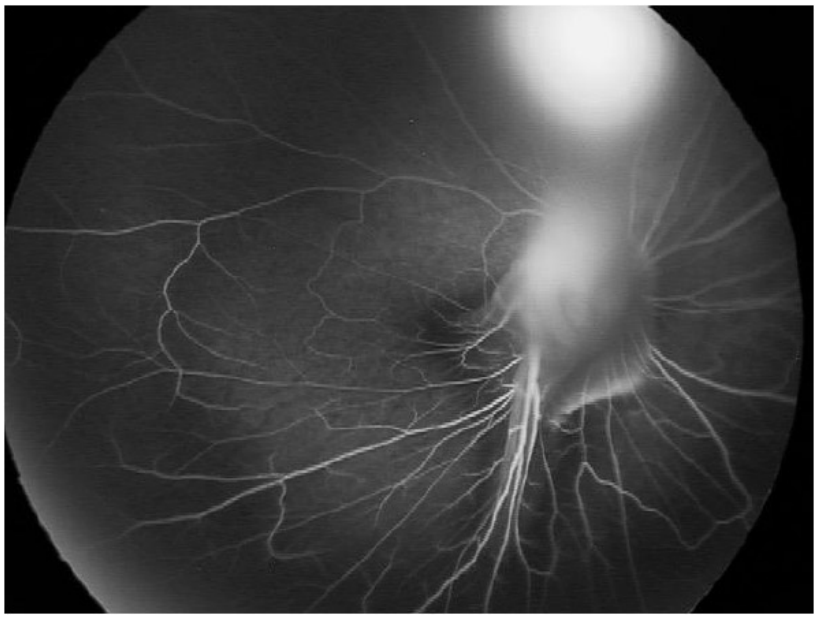

Fig. (3). Persistent fetal vasculature. Widefield fluorescein angiography shows the traction on the retina and an ill-defined macula.

CHAPTER 19

X-Linked Juvenile Retinoschisis

Humberto Ruiz García[1,*] and **Gerardo García-Aguirre**[2,3]

[1] *Clínica Santa Lucía, Guadalajara, Jalisco, Mexico*

[2] *Retina Department, Asociacion para Evitar la Ceguera en Mexico, Mexico City, Mexico*

[3] *Escuela de Medicina - Tecnológico de Monterrey, Mexico City, Mexico*

X-linked juvenile retinoschisis (XLRS) is a degenerative retinal disease that affects males and usually presents early in life. It is relatively common and characteristically presents with mild to severe loss of central vision, radiating foveal streaks, splitting of the inner retinal layers, most prominently in the retinal periphery, and marked reduction of the b-wave amplitude which results in a negative electroretinogram (ERG) [1, 2]. Disease progression is variable even in families with the same mutation. Visual loss can be worsened by complications such as retinal detachment and vitreous hemorrhage. Minor retinal abnormalities can be found in asymptomatic female carriers [3].

XLRS is a disease of the photoreceptors and bipolar cells. It is caused by mutations in the RS1 gene that encodes a 24kDa discoidin-domain containing protein that is secreted as a homo-oligomeric complex. This complex binds to the surface of photoreceptor and bipolar cells where it helps to maintain cellular organization and the structure of the photoreceptor-bipolar cell synapse [4, 5].

More than 190 mutations in the RS1 gene are known to cause XLRS. The extents to which the different mutations affect the structure and function of retinoschisin have enabled further understanding of its importance to retinal function and pathology [4 - 7].

[*] **Corresponding author Humberto Ruiz García:** Clínica Santa Lucía, Manuel Acuña 2941, Guadalajara, Jalisco, Mexico, CP 44689; Tel: +51 (333) 642-8181; E-mail: hruizgarcia@gmail.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

Its prevalence ranges from 1:5,000 to 1:20,000, which makes it one of the more common inherited retinal disorders affecting the macula [1]. Presentation at an early age is usually associated with bilateral reduced visual acuity. Acute loss of vision is associated with complications such as hemorrhage or retinal detachment [6, 7].

ESSENTIALS OF DIAGNOSIS

Ophthalmoscopic evaluation reveals the presence of a spoke wheel pattern in the macula in males under the age of 30 (Fig. **1**). Older patients can present with unspecific retinal abnormalities [8]. Fifty percent or fewer patients may present with peripheral retinoschisis (Figs. **2 - 4**). Other findings such as the Mizuo phenomenon or white flecks have also been described [9, 10].

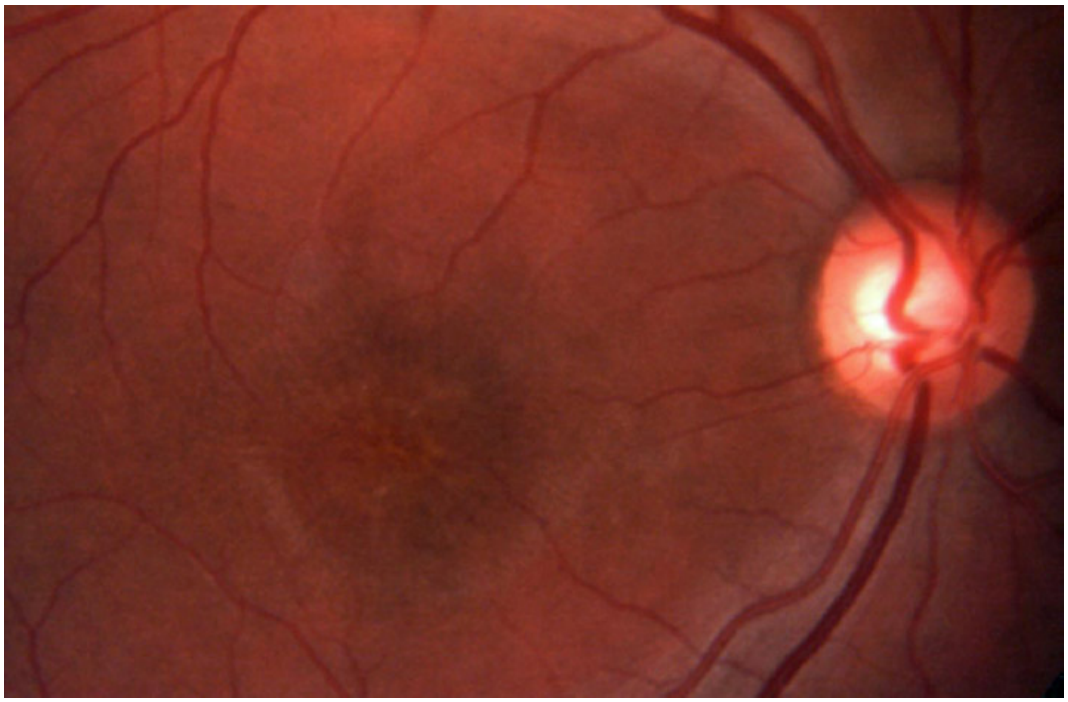

Fig. (1). Color fundus photograph of a 20-year-old male showing the hallmark foveal spoke wheel pattern.

The advent of optical coherence tomography (OCT) has changed the way XLRS is studied and diagnosed, and spectral domain OCT (SD-OCT) has become the mainstay for diagnosis of this disease [11 - 13]. It is relatively easy to obtain even

in young patients, and the tomographic features are very specific to XLRS in pediatric male patients presenting with visual loss (Fig. **5**) [14]. SD-OCT has shown that the area of schisis goes beyond the area observed on ophthalmoscopy and can extend beyond the vascular arcades [15 - 17]. OCT has provided insight into the accurate location of the histologic location of retinal splitting. Cystoid changes involve any retinal layer, mainly the deeper retina (*i.e.*, inner nuclear layer and outer nuclear layer) [18, 19]. Thinning of the nerve fiber layer has also been described. Progressive thinning and epiretinal membrane formation are features of XLRS in older patients that can make the differentiation from other macular dystrophies difficult [20, 21].

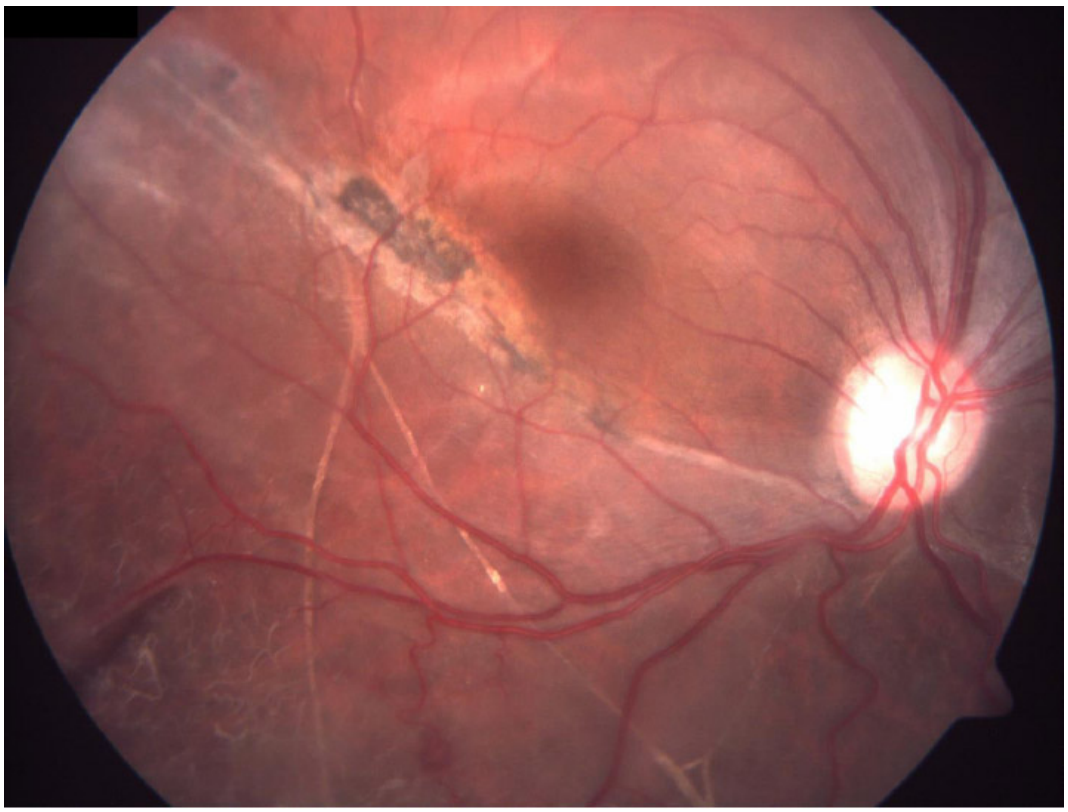

Fig. (2). Color fundus photograph of a 18-year-old male showing inferior retinal schisis that involves the macula. Some intralamellar fibrosis is observed.

Before OCT was available, ERG was the mainstay diagnostic technique for XLRS. A characteristic “negative” ERG pattern observed on dark-adapted retinas

CHAPTER 20

Incontinentia Pigmenti

Mariana Camacho Mendez and **Hugo Quiroz-Mercado***

Ophthalmology Department, Denver Health Medical Center, University of Colorado, Denver, USA

Incontinentia Pigmenti (IP), or Bloch-Sulzberger syndrome, is a rare X-linked dominant syndrome lethal in males characterized by dermatological, ocular, dental, and neurological features [1 - 4]. It is caused by mutations in the NEMO gene located on the q28 portion of X chromosome [5, 6]. This gene is involved in the activation of NFkB, a transcription factor for inflammatory and apoptotic pathway required for many physiological and pathological functions [7 - 9]. The prevalence is 0.7/100,000 [10] and 50-97% of cases have a positive family history [11].

ESSENTIALS OF DIAGNOSIS

IP has four cutaneous stages: Stage 1 is known as vesicular and is characterized by vesiculobullous skin lesions following the lines of Blaschko (Fig. **6**); it presents at birth in 50% of patients (Figs. **10, 11**); stage 2 is reported in 70% of patients with IP and is marked by verrucous lesions appearing between 2 and 6 months of age; stage 3 is characterized by linear brownish pigmentation (Fig. **4**) and atrophy most common in extremities; stage 4 represents the sequelae of IP, characterized by areas of hypopigmentation (Figs. **5, 9**) and alopecia (Fig. **7**) [3, 5, 9].

Histopathology in the early stage shows intraepithelial cleft with eosinophils; the verrucous stage is characterized by hyperkeratosis and acanthosis; and later stages

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

show the typical macrophages containing melanin in the sub-epithelial connective tissue (Fig. **3**) [2].

Ophthalmologic manifestations are present in 35%, and approximately 20% will develop vision threatening disease [1, 4, 10] including strabismus, nystagmus, microphthalmia, iris hypoplasia, cataracts, glaucoma, and optic atrophy [1]. Retinal complications are the most severe and arise as a result of peripheral ischemia with microvasculature abnormalities and neovascularization (Figs. **1, 2, 5, 12**). The presence of retrolental mass with detachment or dysplastic retina is typical [7, 9]. Neurologic manifestations are present in one third of patients with IP, from seizure episodes to severe motor and intellectual impairment [5, 10].

CHAPTER 21

Congenital Prepapillary Vascular Loop

Jose L. Diaz Rubio*

Retina Department, Hospital Star Médica, Aguascalientes, Mexico

A prepapillary vascular loop is a very rare congenital malformation of the vasculature that emerges from the optic nerve. Its incidence is low, ranging from 1 in 2000 to 1 in 9000, and are mostly unilateral. Bilateral loops occur in 9-17% of cases. They are most often asymptomatic and detected in routine ophthalmologic examinations. However, they have been associated with retinal vascular occlusive disease, vitreous hemorrhage, and complications during vitrectomy [1]. Prepapillary optic nerve head loops may be arterial (arteriole), or less commonly, venous (venule). They may occur in and around the optic nerve head, particularly the arteriole, and may bleed into the vitreous [1 - 4].

ESSENTIALS OF DIAGNOSIS

Clinical features: The condition is usually asymptomatic, unless it is complicated with sudden vascular obstruction or bleed [2, 3]. Occlusive events may be facilitated by hemodynamic or intravascular changes associated with exercise and complicated by ischemic events by twisting or thrombosis of the loop [4]. Patients with these complications present with a history of sudden blurred vision, amaurosis fugax, or visual field defect in their eyes [2].

Signs: Loops may take different shapes (hairpin, figure-eight, or corkscrew). They usually emerge from the optic disc, protruding into the vitreous cavity (Fig. **1**). The loops often exhibit movement within the vitreous and cast a shadow on the surrounding fundus. They may be pulsatile. The pathogenesis of the vitreous hemorrhage occurring in and around these loops is uncertain but is probably

* **Corresponding author Jose L. Diaz Rubio:** Retina Department, Hospital Star Médica, Aguascalientes, Mexico; Tel: +52 1 (449) 181 1984; E-mail: joseluisdiazrubio@yahoo.com.mx

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

caused by rupture of small vessels near the base of the loop caused by its movement when pulled by the vitreous. Loops are also associated with branch retinal artery occlusion. Two different mechanisms are thought to be the cause of occlusion: twisting of the loop or thrombosis or following a Valsalva-like mechanism [5 - 7]. The length of the loop is thought to be a key predisposing factor since the twisting of the vessel and turbulent flow encourage thrombus formation [8].

Fig. (1). Color fundus photograph of right optic disk showing prepapillary loop (Image courtesy of Gerardo Garcia-Aguirre, MD).

DIFFERENTIAL DIAGNOSIS

Arterial loops are much more common than venous loops. Fluorescein angiography is the diagnostic method of choice to distinguish between them [8]. Congenital venous vascular loops should be differentiated from acquired dilated venous collateral channels (optocilliary vessels) caused by retinal venous obstruction and meningioma of the optic nerve. Associations between prepapillary vascular loop and persistent fetal vasculature [1] and macroaneurysm [9] have been reported.

MANAGEMENT

Congenital prepapillary vascular loops are usually asymptomatic and do not require treatment. Possible complications are vitreous hemorrhage and venous or arterial thrombosis. When present, vitreous hemorrhage may be treated with pars-plana vitrectomy [3]. Care must be taken to minimize vitreous traction when performing the procedure to avoid breakage of the loop and subsequent intraoperative bleeding, which sometimes may be difficult to control.

CONFLICT OF INTEREST

The author confirms that author has no conflict of interest to declare for this publication.

ACKNOWLEDGEMENTS

Declared none.

CHAPTER 22

Chorioretinal Coloboma

Mitzy E. Torres Soriano[1,2,*] and **Gerardo García-Aguirre**[3,4]

[1] *Retina Department, Ophthalmology Service, Hospital Provincial del Centenario, Rosario, Argentina*

[2] *Centro de la visión Gordon-Manavella, Rosario, Argentina*

[3] *Retina Department, Asociación para Evitar la Ceguera en Mexico, Mexico City, Mexico*

[4] *Escuela de Medicina del Tecnológico de Monterrey, Mexico City, Mexico*

Colobomas occur due to an incomplete closure of the embryonic fissure of the eye, which is supposed to occur during the sixth and seventh weeks of gestation [1], which results in a lack of tissue in the chorid, retina, or both [1]. It is of congenital nature, and may affect other tissues, such as the eyelid, iris, ciliary body and optic nerve [2]. It has an incidence of 0.14% in the general population, and it is associated with a very high risk (up to 40%) of retinal detachment [3].

Colobomas may appear as an isolated finding, or be associated to other conditions, such as neurological disorders, chromosomal disorders, and other syndromes (such as the CHARGE association or Goldenhar syndrome) [4 - 7].

ESSENTIALS OF DIAGNOSIS

Chorioretinal colobomas are in many instances asymptomatic. Symptoms vary according to the ocular structures affected. Complications are frequent and may profoundly affect visual acuity, especially if the macula or the optic disc are involved. Visual field defects are rarely perceived by the patient due to the

[*] **Corresponding author Mitzy E. Torres Soriano:** Centro de la Vision Gordon - Manavella, Montevideo 763, CP 2000, Rosario - Santa Fe, Argentina; Tel/Fax: +54 (341) 4400239/4244850; E-mail: mitzytorres@yahoo.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

congenital nature of this condition. However, choroidal neovascularization or retinal detachment are common complications that can cause further reduction of visual acuity later in life.

Most colobomas are readily apparent in ophthalmologic examination. They appear as a yellowish lesion with well-defined circular borders, almost always in the inferior part of the globe, where there is a trace of hypoplastic retinal tissue (known as *intercalary membrane*), and no retinal pigment epithelium or choroid. The sclera is thin, usually producing a staphyloma (Figs. **1**-**3**, **5**).

Fig. (2). Fundus photographs of inferonasal chorioretinal coloboma.

CHAPTER 23

Bergmeister Papilla

Jose L. Diaz Rubio*

Retina Department, Hospital Star Médica, Aguascalientes, Mexico

The term "Bergmeister papilla" refers to the presence of fibrous glial tissue just anterior to the optic disc. It is present since birth, and it is a remnant of the fibrous sheath that normally surrounds the hyaloid artery during fetal life as it arises from the optic disc. This tissue is called the central supporting tissue meniscus of Kuhnt [1].

ESSENTIALS OF DIAGNOSIS

Clinical features: Bergmeister's papilla is usually asymptomatic, the visual acuity is unaffected by the abnormality, and systemic associations are generally lacking [1, 2].

Signs: A small mass of glial tissue takes the form of a veil-like membrane overlying the optic disc, it is also referred to as epipapillary membrane (Figs. **1** and **2**). The glial tissue often fills in the optic cup such that the cup is obliterated; a visible white, fibrous remnant that is seen on ophthalmoscopy to overlay the optic disc. The nasal side of the disc is more frequently involved than the temporal side. Absence of physiologic cupping can also be seen in affected eyes [1, 2].

DIFFERENTIAL DIAGNOSIS

Differential diagnosis should be with diseases that can produce peripapillary membranes, such as ischemic retinopathies; however, these membranes are

* **Corresponding author Jose L. Diaz Rubio:** Retina Department, Hospital Star Médica, Aguascalientes, Mexico; Tel: +52 1 (449) 1811984; E-mail: joseluisdiazrubio@yahoo.com.mx

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

accompanied by retinal alterations and the membranes are vascularized. Bergmeister papilla is avascular.

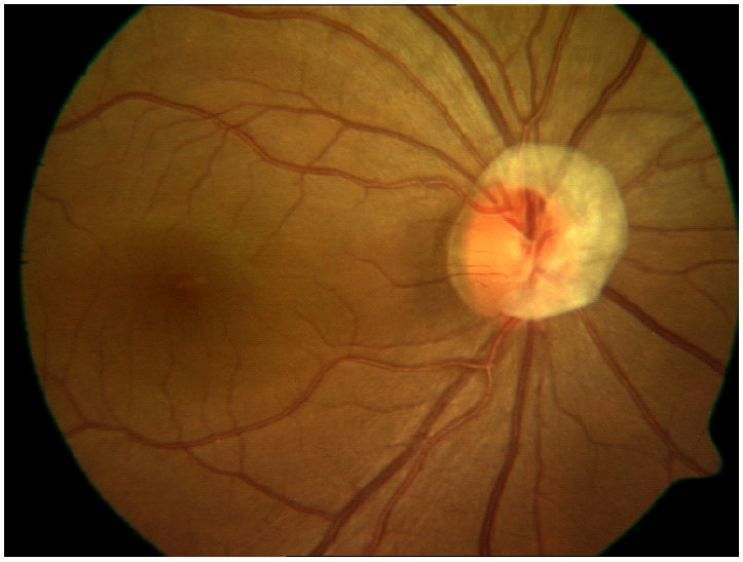

Fig. (1). Bergmeister's papilla. Presence of fibrous tissue anterior to the optic disc (Photograph courtesy of the Pathology Department Image Archive, Asociación para Evitar la Ceguera en México).

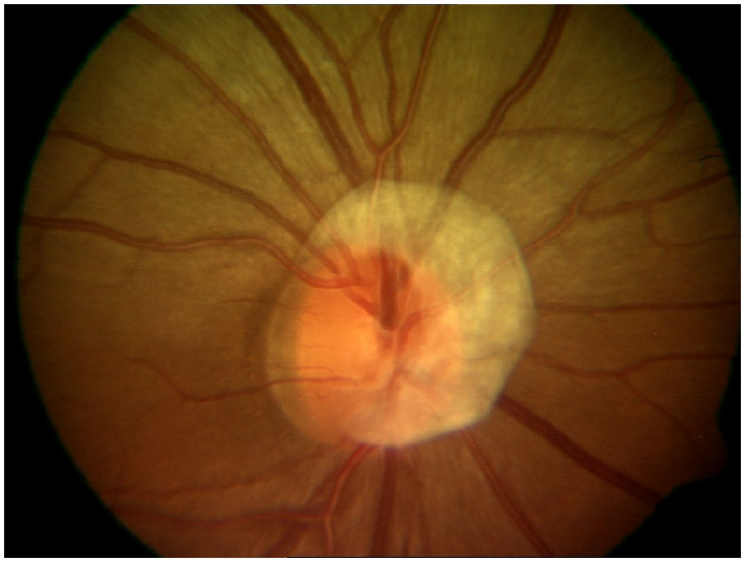

Fig. (2). Close up of Fig. (**1**) , showing a thin veil-like membrane anterior to the optic disc, affecting predominantly the nasal side (Photograph courtesy of the Pathology Department Image Archive, Asociación para Evitar la Ceguera en México).

One publication reports association with aniridia, microcornea, and myopia [3]. Optic Coherence Tomography (OCT) provides non-invasive visualization of the fibrous tissue and its relation with the vitreoretinal interface [4].

MANAGEMENT

Bergmeister's papilla by itself does not require treatment, does not affect visual acuity, and does not produce symptoms.

CONFLICT OF INTEREST

The author confirms that author has no conflict of interest to declare for this publication.

ACKNOWLEDGEMENTS

Declared none.

CHAPTER 24

Optic Disc Pit

Maria Daniela Malave[1] and **Gema Ramirez**[2,*]

[1] *Unidad UOPRED, C.A. Centro Médico Guerra Mendez, Valencia, Venezuela*

[2] *Centro de Cirugía Oftalmológica (CECOF), Caracas, Venezuela*

Optic disc pit (ODP) is a rare, congenital excavation of the optic nerve head, described by Wiethe in 1882 [1]. Usually seen in association with other abnormalities including large optic nerve head size, large inferior colobomas of the optic disc, and retinal colobomas. These associations may suggest a common origin, caused by an incomplete closure of the embryonic fissure [2].

ESSENTIALS OF DIAGNOSIS

A congenital ODP is usually a solitary, whitish depression, usually located in the inferotemporal portion of the optic disc (Fig. **1**). It may be asymptomatic, but may also be associated to serous retinal detachment or cystoid retinal edema in the macular area [3, 4]. Presence of a pit and serous detachment is really uncommon at the nasal margin of the optic disc (Figs. **4**-**7**). It may occur bilaterally in 10 to 15% of cases and may be inherited as an autosomal dominant abnormality [5].

Approximately one-half to two-thirds of optic disc pits are associated with maculopathy, classically, serous retinal detachment. The maculopathy can be discovered on slit-lamp funduscopic examination or with direct or indirect ophthalmoscopy [1 - 3]. Fluorescein angiography and OCT may provide further elucidation [1, 4, 6] (Fig. **2**).

CHAPTER 25

Tilted Disc Syndrome

Lihteh Wu[*], **Christina Pagano** and **Max Wu**

Asociados de Macula Vitreo y Retina de Costa Rica, Costa Rica

The tilted disc syndrome is a non-hereditary congenital anomaly arising from an incomplete closure of the fetal fissure [1]. According to a population-based study, the prevalence of tilted discs was found to be associated with astigmatism and the degree of myopia [2]. In this study, the general prevalence of tilted disc was 1.6%. However, the prevalence increased from 0.1% when the astigmatism was ≤ 1 D to 17.9% when the astigmatism was ≥ 5 D. Myopia was present in 66.2% of eyes with tilted disc compared to 12.4% of eyes with a normal disc appearance.

ESSENTIALS OF DIAGNOSIS

The diagnosis of a tilted disc is a clinical one and is made with ophthalmoscopy. The superotemporal optic disc is elevated, whereas the inferonasal portion of the disc is displaced posteriorly. This leads to an oval appearing disc with its long axis in an oblique orientation. The retinal vessels exit the nerve nasally rather than temporally (situs inversus). An inferior or inferonasal crescent is often present as well. An inferonasal staphyloma characterized by RPE and choroidal thinning is also present (Figs. **1**, **2** and **3**).

DIFFERENTIAL DIAGNOSIS

- Optic Nerve Hypoplasia
- Chiasmal Syndrome

[*] **Corresponding author Lihteh Wu:** Asociados de Macula Vitreo y Retina de Costa Rica, Costa Rica; Tel: (506) 2222-1115; E-mail: LW65@cornell.edu

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

Fig. (1). Colour fundus photograph of a right eye with a tilted disc. The retinal vessels exit the nerve nasally rather than temporally (situs inversus). Notice the staphyloma in the inferior macula.

Fig. (2). Infrared reflectance image of the same eye as in Fig. (**1**). Notice that the area of the staphyloma is slightly out of focus.

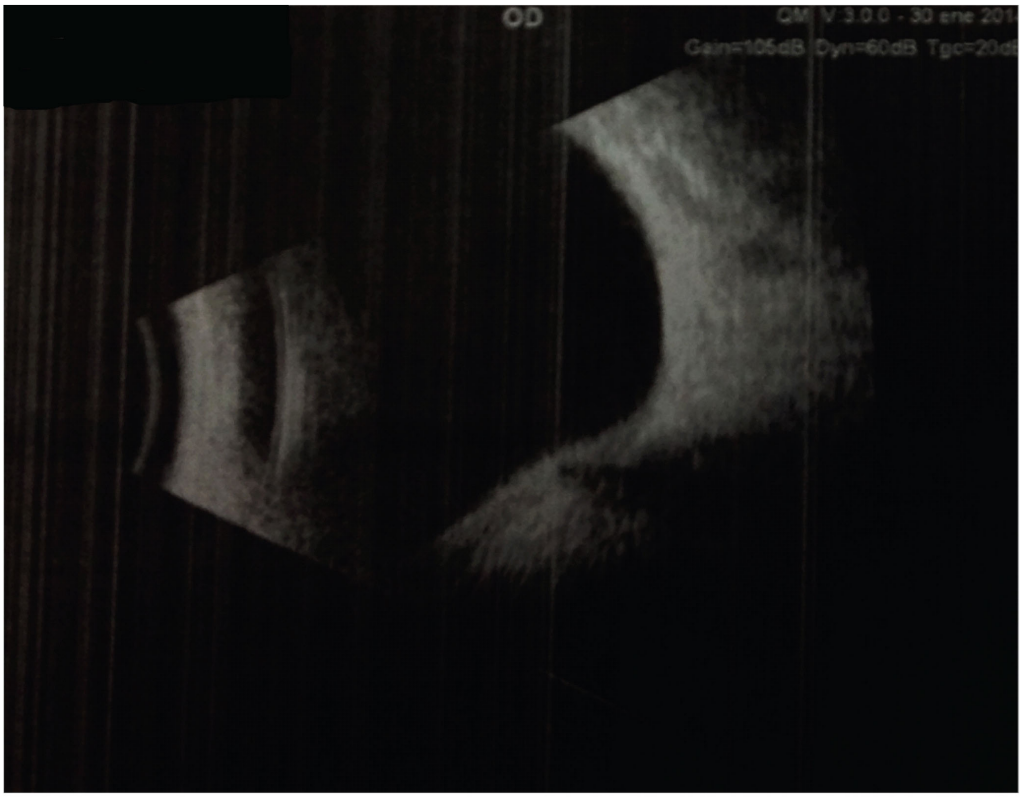

Fig. (3). B Scan ultrasound of the same eye as in Figs. (**1** and **2**). This demonstrates that there is no retinal detachment and an inferior staphyloma is present.

MANAGEMENT

The management of the tilted disc syndrome is directed towards differentiating it from a chiasmal syndrome. Unlike compressive lesions of the chiasm, the visual field defects in the tilted disc syndrome do not progress nor respect the vertical midline. In some cases, the visual field defect may improve or even disappear by increasing the myopic correction [3]. In equivocal cases neuroimaging is indicated.

Eyes with tilted disc syndrome often have macular complications when the inferior staphyloma crosses the macula [4]. Choroidal neovascularization (CNV), serous retinal detachment (SRD), RPE atrophy, and polypoidal choroidal vasculopathy (PCV) have all been reported [4]. It is speculated that the different radii of curvature between the globe and the staphyloma lead to tractional forces

CHAPTER 26

Retinitis Pigmentosa

Andrée Henaine-Berra[1,*] and **Gerardo García-Aguirre**[2,3]

[1] *Hospital General "Dr. Manuel Gea González", Mexico City, Mexico*

[2] *Retina Department, Asociación para Evitar la Ceguera en Mexico, Mexico City, Mexico*

[3] *Escuela de Medicina del Tecnológico de Monterrey, Mexico City, Mexico*

Retinitis pigmentosa (RP) is the most common retinal dystrophy worldwide, with a prevalence of 1 in 4000 individuals [1]. It comprises a heterogeneous group of inherited retinal disorders with degeneration of the photoreceptors and the retinal pigment epithelium (RPE), characterized by nyctalopia and visual field constriction, leading to progressive visual loss [1, 2]. RP can be inherited as an autosomal dominant, autosomal recessive or X-linked trait [1 - 3].

The word "retinitis" is controversial because it indicates inflammation, which is not observed in the course of the disease [4]. In some countries, the term "retinosis" has also been adopted [3].

ESSENTIALS OF DIAGNOSIS

The age of onset of RP ranges from infancy to adulthood [1]. Difficulties with dark adaptation are the initial symptom, and as the disease progresses, peripheral vision loss occurs causing tunnel vision, progressing to central vision loss [1, 3].

At early stages, mild RPE changes suggesting atrophy are observed. Vitreous cells are always seen from the beginning of the disease. Pigmentary changes (which usually are distributed in a pattern that resembles bone spicules) start at the equator and slowly progress to the posterior pole and the periphery (Figs. **1**-**7**).

CHAPTER 27

Best's Disease

Steven S. Saraf[1], **Robert A. Prinzi**[1] and **Michael D. Ober**[1,2,*]

[1] *Department of Ophthalmology, Henry Ford Health System, Detroit, MI, USA*

[2] *Retina Consultants of Michigan, Southfield, MI, USA*

Best disease is an autosomal dominant maculopathy associated with a mutation in the Bestrophin (BEST1) gene.

ESSENTIALS OF DIAGNOSIS

Although its clinical appearance may vary, it classically is known for a vitelliform or "egg-yolk" lesion centered in the macula of each eye. At this stage, the lesions are typically round, solitary, yellow, slightly raised, and often asymmetric [1] (Figs. **1** and **2**). The mutations in the BEST1 gene show variable penetrance and expressivity with carriers developing a range of findings from no clinical signs to manifestations such as multi-focal Best disease [1]. It is therefore important when making a definitive diagnosis to employ other diagnostic methods such as electrooculogram (EOG), optical coherence tomography (OCT), or genetic testing.

Lesions tend to go through a characteristic progression of the disease beginning with a normal appearing fundus at birth. Sharply demarcated yellow macular lesions develop in early childhood (vitelliform stage). Lesions may become large, but surprisingly, despite dramatic anatomic changes, the vision is usually very good. Breakdown of the vitelliform deposit leads to separation of the photoreceptors from the RPE (Fig. **3**). Vision loss may occur at this point, but often develops later with absorption of vitelliform material leading to RPE and/or

* **Corresponding author Michael D. Ober:** 29201 Telegraph Road, Suite 606, Southfield, MI 48034, USA; Tel: (248) 356-6473; Fax: (248) 356-6473; E-mail: obermike@gmail.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

photoreceptor degeneration. Patients in the atrophic stage are susceptible to choroidal neovascularization (CNV) and/or fibrotic scarring. Vision is usually fairly well preserved into adulthood, at least in one eye. However, slowly progressive central visual impairment is not uncommon after the age of 60 [2].

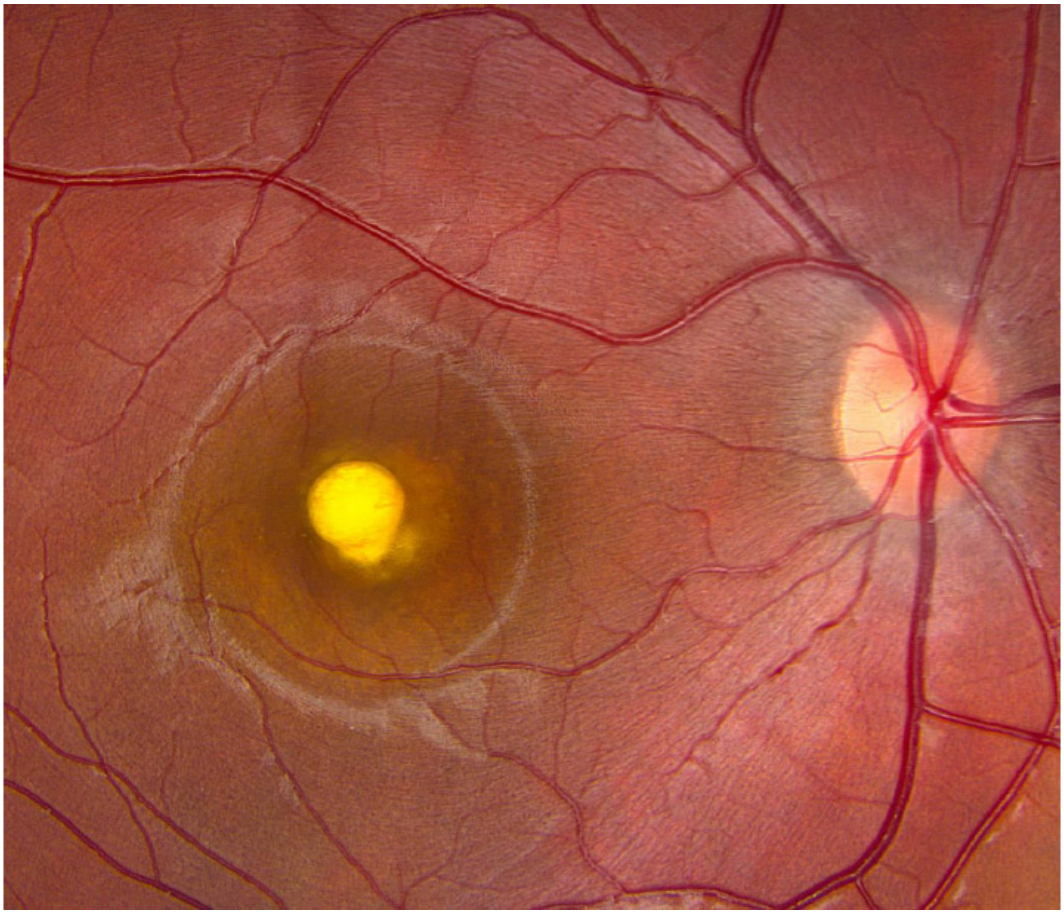

Fig. (1). Colour fundus photograph of the right eye demonstrating the classic "egg-yolk" appearance of the macula.

The mutation responsible for Best's Disease was first cloned by Petrukhin *et al.* in 1998 [3]. It is expressed primarily on the basolateral plasma membrane of the RPE and functions as a calcium-dependent chloride channel, which is believed to regulate the flow of chloride, bicarbonate, and calcium ions across the RPE membrane [4, 5]. Calcium aids in regulation of RPE functions including

epithelium adhesion to the photoreceptors and phagocytosis of photoreceptor outer segments. Although the underlying mechanism is controversial, some authors believe that mutations in BEST1 lead to separation of RPE from the retina with poorly phagocytized outer segments accumulating in the potential space and forming lipofuscin. Eventually this leads to the formation of the characteristic vitelliform lesion seen on examination [6].

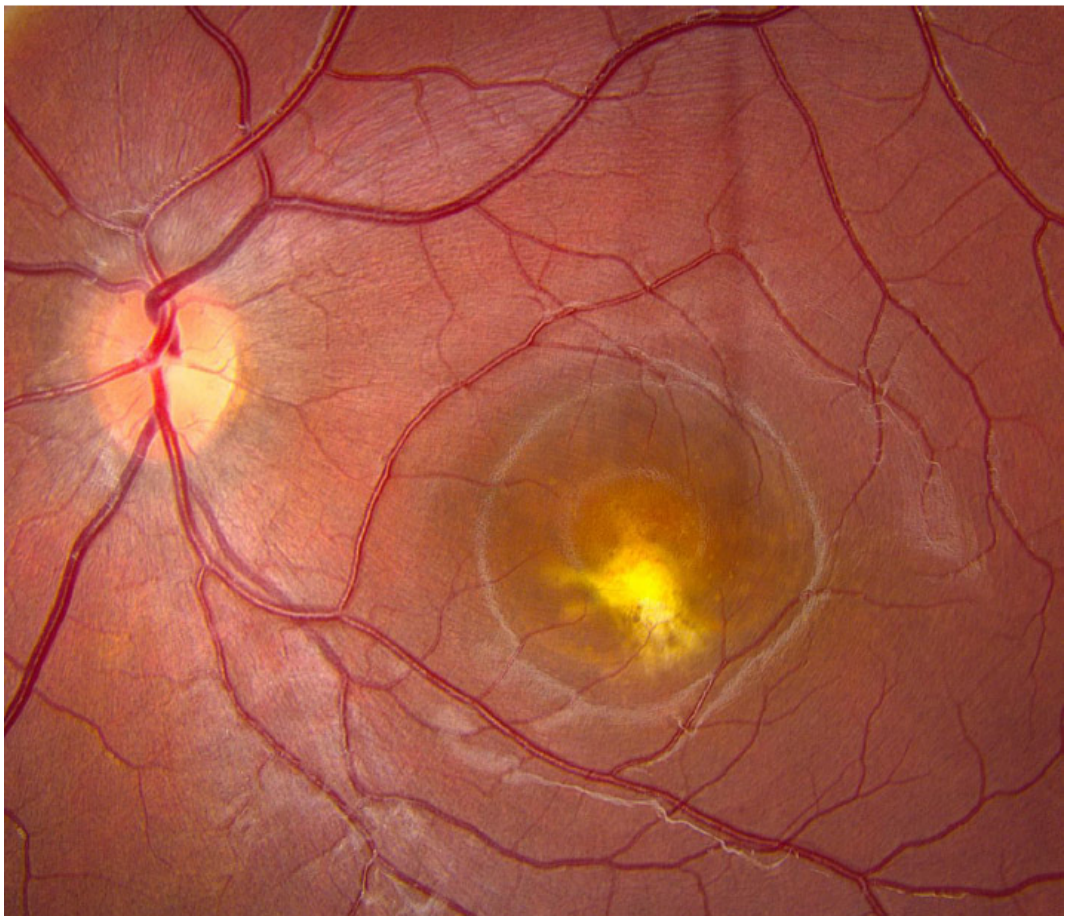

Fig. (2). Colour fundus photograph. The left eye of the same patient demonstrates a "scrambled-egg" appearance.

The molecular basis of Best disease directly affects the electrical potentials measured across Bruch's membrane. Changes in the chloride ion channel lead to an abnormal EOG, typically recorded as a diminished Arden ratio (AR). The AR

CHAPTER 28

Stargardt's Disease

Mitzy E. Torres Soriano[1,2,3,*] and **Manuel Torres López**[1]

[1] *Unidad Oftalmológica "Dr. Torres López", Centro Médico Cagua, Aragua, Venezuela*

[2] *Centro de la Visión Gordon-Manavella, Rosario, Argentina*

[3] *Clínica de Ojos "Dr. Carlos Ferroni", Rosario, Argentina*

Originally described by Stargardt in 1909 [1], Stargardt's macular dystrophy (SMD) is a chronic and progressive disease that affects the macula in young patients. Its mode of inheritance is autosomal recessive, and is caused by a mutation in the ABCA4 gene [2 - 4]. Mutations in this gene may cause classic SMD, fundus flavimaculatus (which is a variant of SMD) and are associated to several other disorders, such as cone-rod dystrophy and retinitis pigmentosa [3, 5, 6]. Individuals heterozygous for ABCA4 mutations may also be in greater risk of having age-related macular degeneration [7].

Stargardt's disease (including fundus flavimaculatus) is one of the most common causes of macular disease in childhood and accounts for 7% of all retinal dystrophies [8]. Disease prevalence is around 1 in 10, 000 [9]. First symptoms appear early in childhood or adolescence. The disease affects males and females alike, without predilection for race.

ESSENTIALS OF DIAGNOSIS

Similar to other dystrophies, patients with SMD are asymptomatic when the disease is in its early stages. Eventually, patients complain of decreased central vision, photophobia, abnormal color vision and slow dark adaptation. Slit lamp examination shows a typical clinical picture, where pigment changes with a

* **Corresponding author Mitzy E. Torres Soriano:** Centro de la Visión Gordon - Manavella, Montevideo 763, CP 2000, Rosario - Santa Fe, Argentina; Tel/Fax: +54 (341) 4400239/4244850; E-mail: mitzytorres@yahoo.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

greenish discoloration are observed in the central macula [1 - 4]. Flecks, which are the yellow-white lesions characteristic of fundus flavimaculatus, may or may not be present (Figs. **1** and **2**). In later stages, the macula is often described as having a "beaten bronze" appearance. However, disease phenotype may be highly variable [2].

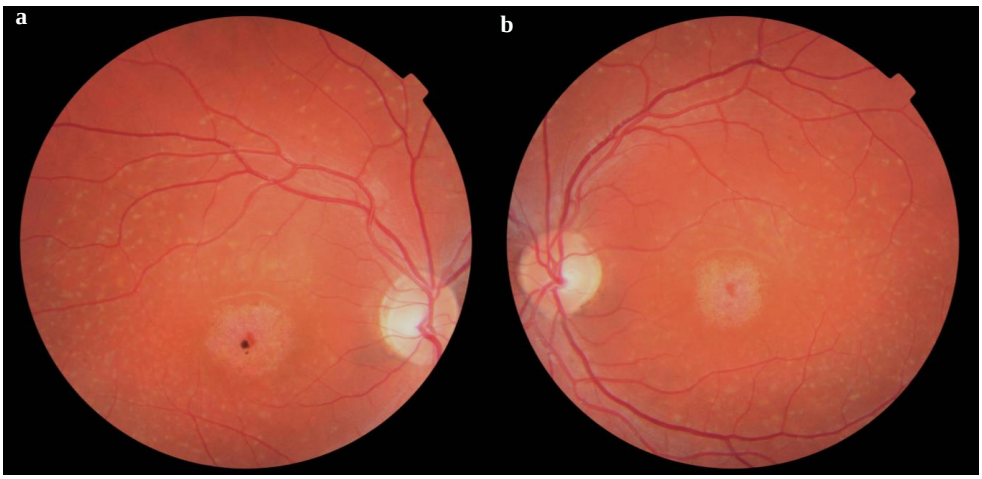

Fig. (1). Colour fundus photographs. (**A**) and (**B**) 25-year-old female with Stargardt disease. Note the diffuse yellow pisciform flecks in posterior pole and central macular atrophy in both eyes.

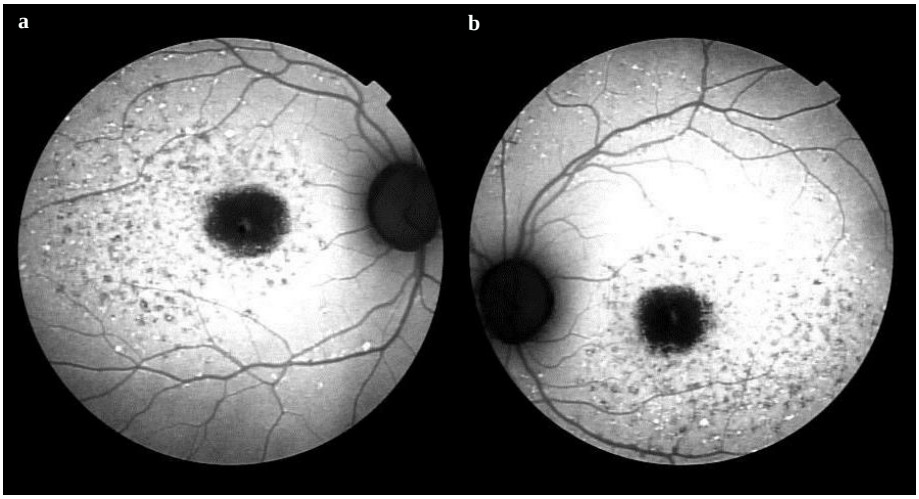

Fig. (2). (**A**) and (**B**) Autofluorescensce of the same patient of Fig. (**1**). Pisciform lesions and macular atrophy.

Patients with fundus flavimaculatus (retinal flecks without macular atrophy) often have a later disease onset and slower visual deterioration [4].

Visual field testing is often normal early in the disease. Eventually, central scotomas are observed, which progress to absolute scotomas over time.

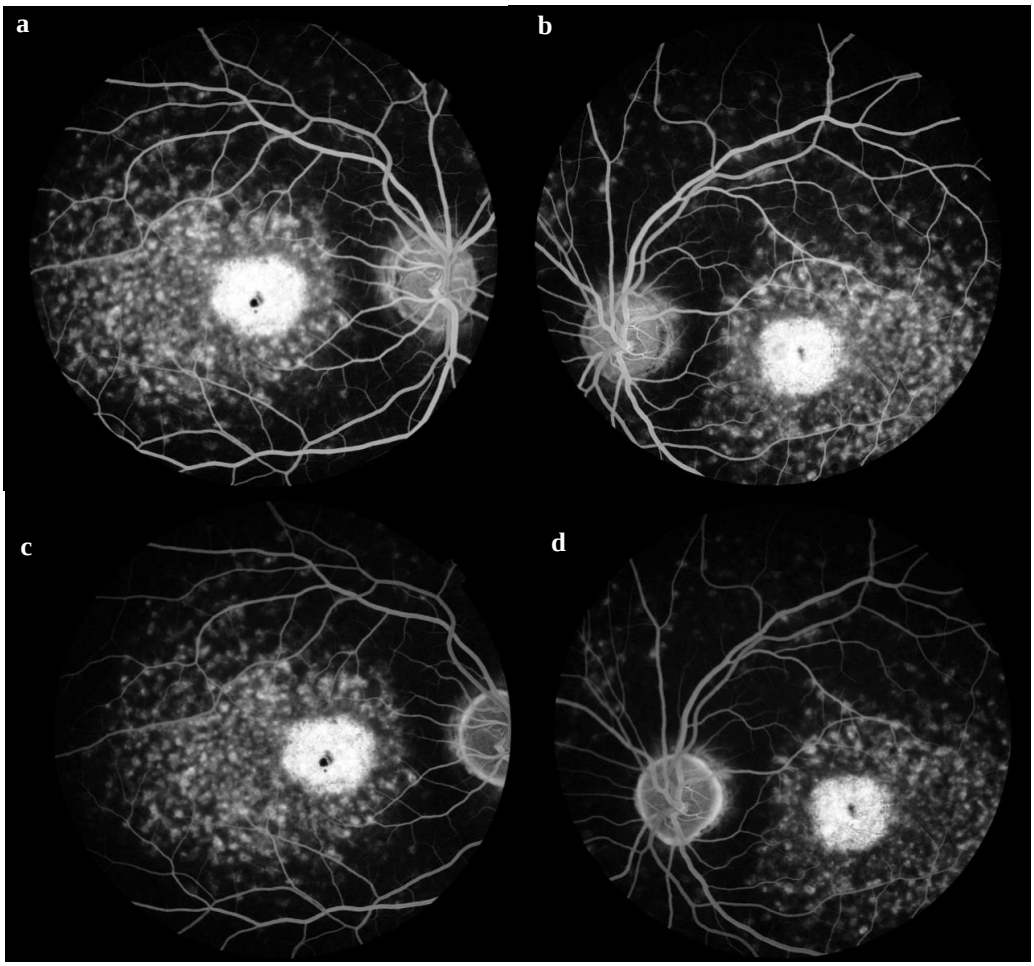

Fig. (3). Fluorescein angiography showing silent choroid Stargardt's disease (**A-D**) and central ovoid zone of hyperfluorescence, surrounded even in the early stages (**A** and **B**) by some hyperfluorescent flecks.

An acquired red-green dyschromatopsia may be characteristic in these patients with color testing. Fluorescein angiography in early cases shows a central ovoid zone of hyperfluorescence, mostly surrounded even in the early stages by some

CHAPTER 29

Choroideremia

Mitzy E. Torres Soriano[1,2,3,*]

[1] *Retina Department, Ophthalmology Service, Hospital Provincial del Centenario, Rosario, Argentina*

[2] *Centro de la Visión Gordon-Manavella, Rosario, Argentina*

[3] *Clínica de Ojos "Dr. Carlos Ferroni", Rosario, Argentina*

Choroideremia (CHM) is an X-linked degeneration of the choroid, retinal pigment epithelium (RPE), and retina caused by deletion or mutation of the CHM gene, encoding Rab escort protein-1 (REP1) [1, 2]. The estimated prevalence is 1 in 50,000 in the general population [3].

For many years it was assumed that the basic abnormality in choroideremia was a vasculopathy causing primary choriocapillaris atrophy. However, histo-pathological studies of choroideremia and studies of the localization of the CHM protein place the basic defect in the RPE [4, 5].

ESSENTIALS OF DIAGNOSIS

Since it is a X-linked recessive disease, only males are affected, and females are carriers. The first symptom is nyctalopia, which ensues in the first decade of life, followed by progressive visual field loss [3]. As the disease progresses, pigment changes and areas of choroidal atrophy begin to appear in the equator. At the end stages of the disease, there is generalized chorioretinal atrophy, with some degree of preservation of the choroidal vasculature in the macula and the far periphery. (Figs. **1, 2** and **3a**). In advanced stages, the retina and choroid are so atrophic that the sclera becomes visible.

[*] **Corresponding author Mitzy E. Torres Soriano:** Centro de la Visión Gordon - Manavella, Montevideo 763, CP 2000, Rosario - Santa Fe, Argentina; Tel/Fax: +54 (341) 4400239/4244850; E-mail: mitzytorres@yahoo.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

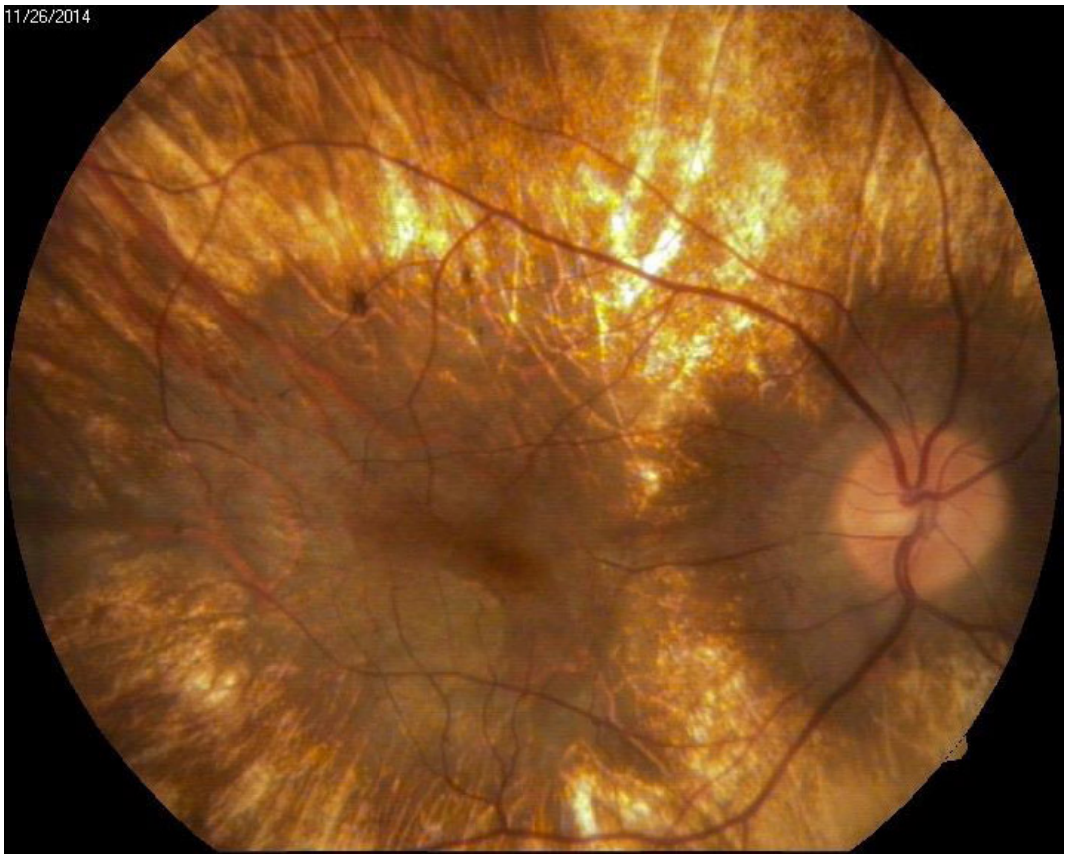

Fig. (1). Right eye fundus photography of male patient with diagnosis of Choroideremia. There is atrophy of the retinal pigment epithelium and choroid with exposure of the sclera and large choroidal blood vessels. Preservation of the central macula and near the optic disc are shown (Courtesy of Andrée Henaine Berra MD, Mexico).

Autofluorescence is decreased in the areas of chorioretinal atrophy with some relative hyperautofluorescence in the preserved retinal tissue. Fluorescein angiography (FA) shows atrophy of the retinal pigment epithelium with the scalloped areas of missing choriocapillaris appearing hypofluorescent next to brightly hyperfluorescent areas of patent choriocapillaris (Fig. **3b**). OCT reveals absence of the outer nuclear layer, ellipsoid layer, RPE and choroid [6, 7]. The ERG and EOG are abnormal early in the course of the disease and ERG is generally extinguished by midlife. However, there can be intrafamilial and interfamilial variabilities of ERG responses [6 - 10].

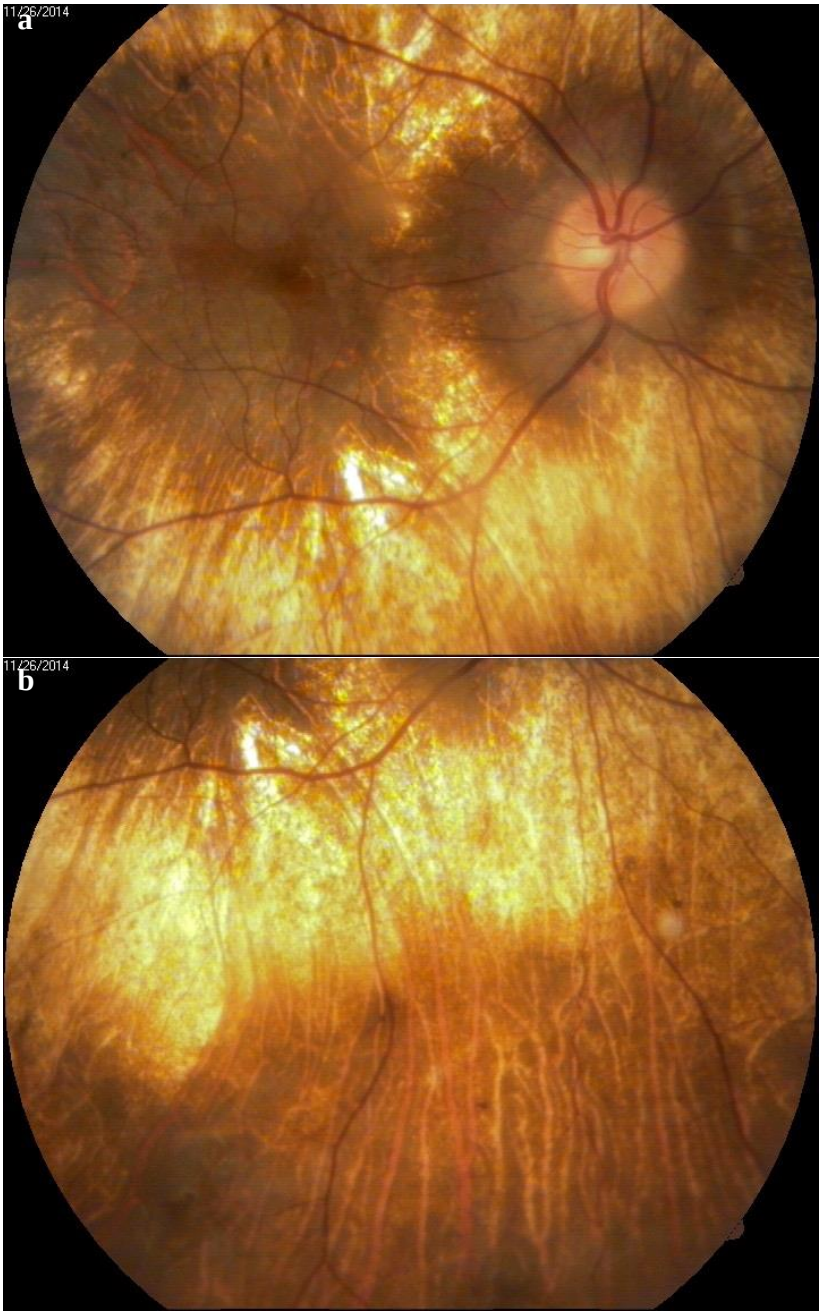

Fig. (2). Colour fundus photographs. The same patient as shown as Fig. (**1**). (**a** and **b**) There are RPE and choroidal atrophy in the equatorial and peripheral fundus, loss of choriocapillaris, and bare sclera (Courtesy of Andrée Henaine Berra MD, Mexico).

CHAPTER 30

Gyrate Atrophy

Mitzy E. Torres Soriano[1,2,3,*]

[1] *Retina Department, Ophthalmology Service, Hospital Provincial del Centenario, Rosario, Argentina*

[2] *Centro de la Visión Gordon-Manavella, Rosario, Argentina*

[3] *Clínica de Ojos "Dr. Carlos Ferroni", Rosario, Argentina*

Gyrate atrophy (GA) of the choroid and retina is a rare, autosomal recessive, chorioretinal dystrophy [1] that causes progressive chorioretinal atrophy due to hyperornithinemia resulting from ornithine d-aminotransferase (OAT) deficiency [2]. Many different OAT gene mutations have been described [3 - 5]. The actual cause of chorioretinal atrophy remains unknown [6].

ESSENTIALS OF DIAGNOSIS

The initial symptoms are reduction of peripheral vision and, in some patients, reduction of night vision (nyctalopia) in the first decade of life [7].

Loss of central vision occurs in patients over 40-50 years old [8], and their fundus reveals very well demarcated circular or ovoid areas of chorioretinal atrophy in the mid-periphery. These lesions have a hyperpigmented margin (Figs. **1** and **2**) [2]. With increasing age, these lesions grow in size and number, eventually coalescing (Fig. **2**) and involving the entire posterior pole.

Myopia, posterior subcapsular cataracts and cystoid macular edema may also occur [2, 9].

There is no autofluorescence in the atrophic areas. Fluorescein angiography (FA) demonstrates the sharp demarcation between normal and abnormal tissue, the

* **Corresponding author Mitzy E. Torres Soriano:** Centro de la Visión Gordon - Manavella, Montevideo 763, CP 2000, Rosario - Santa Fe, Argentina; Tel/Fax: +54 (341) 4400239/4244850; E-mail: mitzytorres@yahoo.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

former showing normal background fluorescence; the latter, atrophy of the choriocapillaris (Fig. **2**). Full-field electroretinogram shows severely reduced or undetectable amplitudes even at an early stage. OCT can be useful for detecting cystoid macular edema.

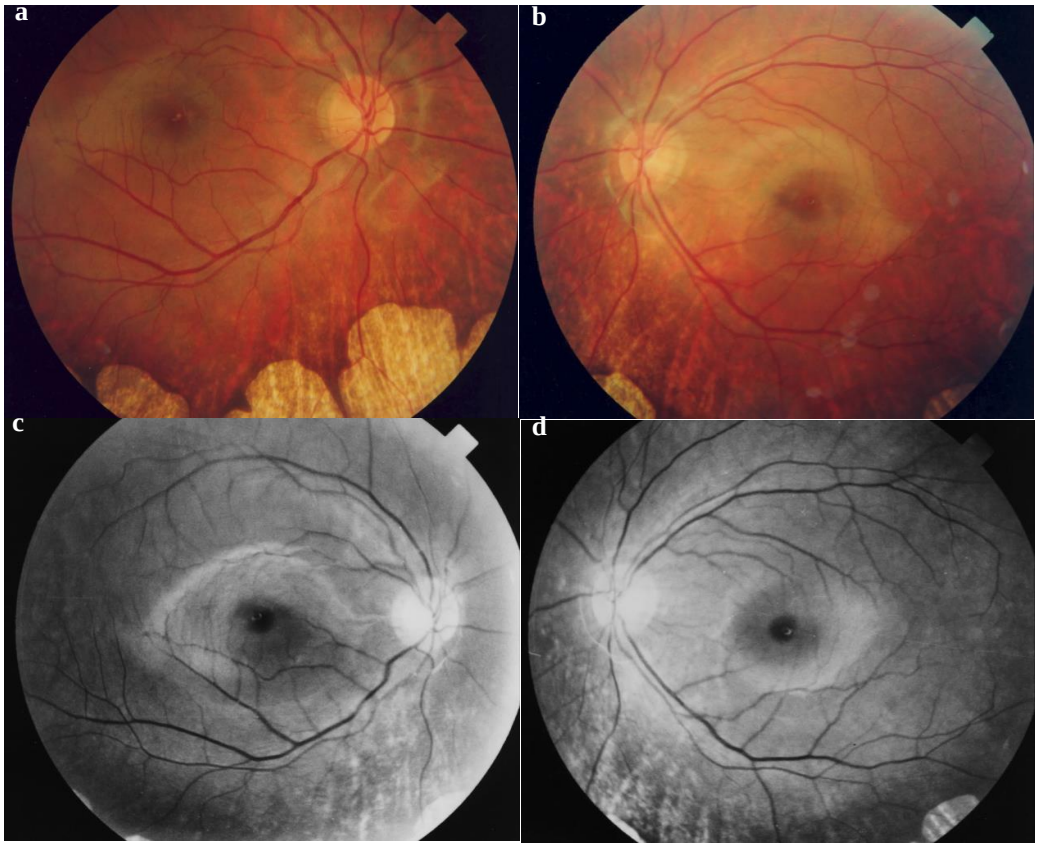

Fig. (1). Fundus photographs: Gyrate atrophy. (**a**) and (**b**) There are sharply defined areas of chorioretinal atrophy separated from each other by thin margin of pigment. (**c**) and (**d**) Red free images of the same patient (Courtesy of Juan Manuel Jiménez-Sierra, MD).

Patients present very high levels of serum, urine, and spinal fluid ornithine (10 to 20 times normal). Usually the typical fundus findings are sufficiently characteristic to make the diagnosis of GA.

In patients with suspected GA, serum ornithine concentration should be measured to confirm hyperornithinemia. Molecular genetic testing of the OAT gene can be

useful for confirming the diagnosis.

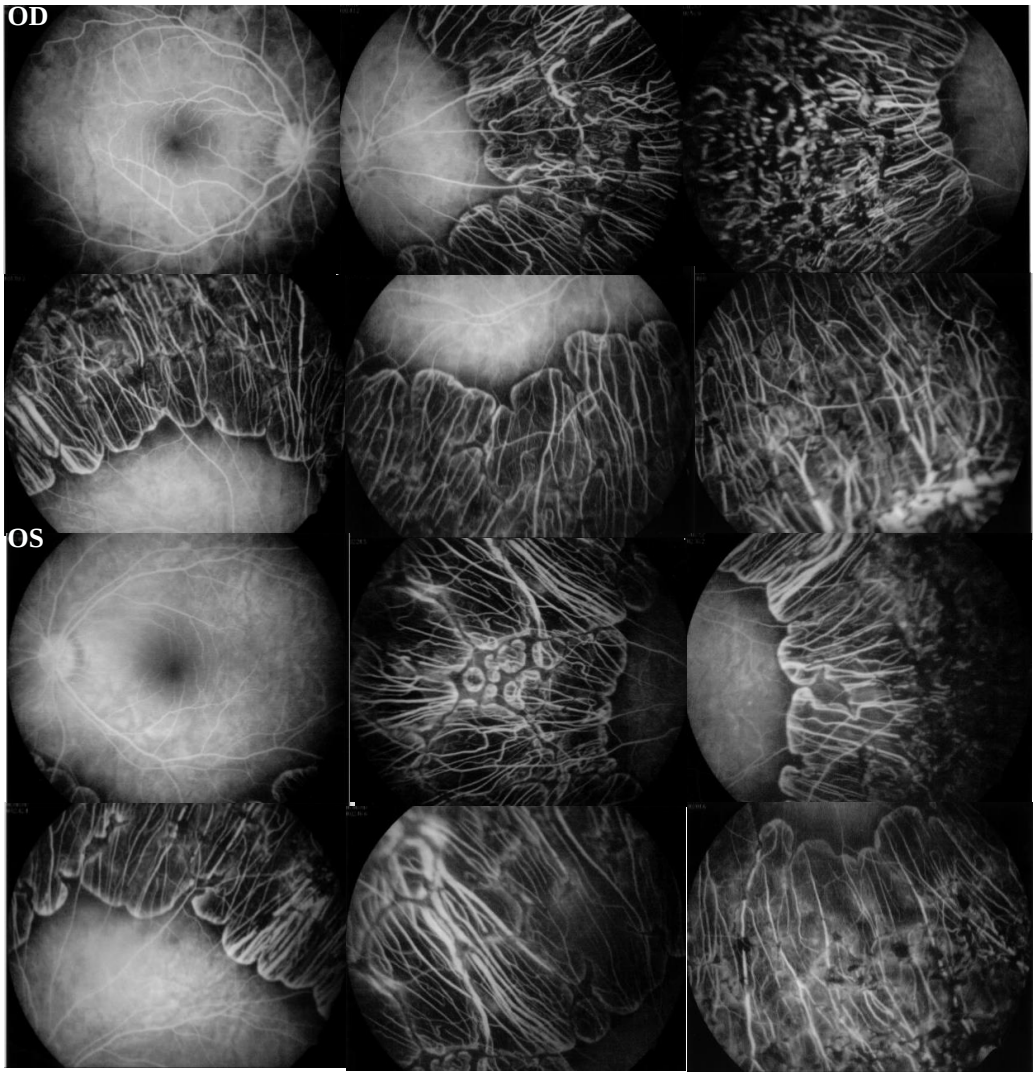

Fig. (2). Fluorescein angiography of the same patient of Fig. (**1**), after 5 years of follow up. The areas of choroidal atrophy show choriocapillaris atrophy on the angiogram and slight leakage at the margin of chorioretinal atrophy. Adjacent areas of normal-appearing retina have a normal background choroidal flush (Courtesy of Juan Manuel Jiménez-Sierra, MD).

DIFFERENTIAL DIAGNOSIS

When GA reaches its final stages, it may not be differentiable from advanced

CHAPTER 31

Cone-Rod Dystrophy

Mitzy E. Torres Soriano[1,2,3,*]

[1] *Retina Department, Ophthalmology Service, Hospital Provincial del Centenario, Rosario, Argentina*

[2] *Centro de la visión Gordon-Manavella, Rosario, Argentina*

[3] *Clínica de Ojos "Dr. Carlos Ferroni", Rosario, Argentina*

Dystrophies are inherited conditions, not congenital, usually bilateral, often symmetric and progressive, which develop on a retina with characteristic normal birth [1]. Prevalence of cone-rod dystrophy (CRD) is estimated at 1:40.000 [2]. All modes of Mendelian inheritance have been reported, and currently 17 genes and some additional loci have been reported. ABCA4 seems to be the most prominent causal gene; however, the etiologic fraction for this gene varies widely between studies (24%-65%) [3 - 9].

ESSENTIALS OF DIAGNOSIS

In this group of dysthrophies, the photoreceptors most affected are the cones and rods, which can commit secondarily. The most common initial symptomatology is photophobia, low vision and dyschromatopsia, and in some cases, nyctalopia, when the rod cells are affected [10]. The age of onset is variable; most patients present during the first two decades of life. Visual prognosis depends on age of onset, being worse if the disease is diagnosed earlier in life [11]. The fundus may be normal or progress to atrophic changes above all in the macula, resembling Bull's eye maculopathy, with areas of retinal pigment epithelium (RPE) atrophy that may extend beyond the temporal arcades, and develop areas of retinal atrophy

* **Corresponding author Mitzy E. Torres Soriano:** Centro de la Visión Gordon - Manavella, Montevideo 763, CP 2000, Rosario - Santa Fe, Argentina; Tel/Fax: +54 (341) 4400239/4244850; E-mail: mitzytorres@yahoo.com

Mitzy E. Torres Soriano, Gerardo García-Aguirre, Maximiliano Gordon & Veronica Kon Graversen (Eds.)

similar to pigmentary retinitis (Fig. **1**) [10 - 12]. The optic disc may show a variable degree of pallor. It may also develop retinal vascular attenuation and peripheral pigmentary deposits resembling bone spicules [10 - 12].

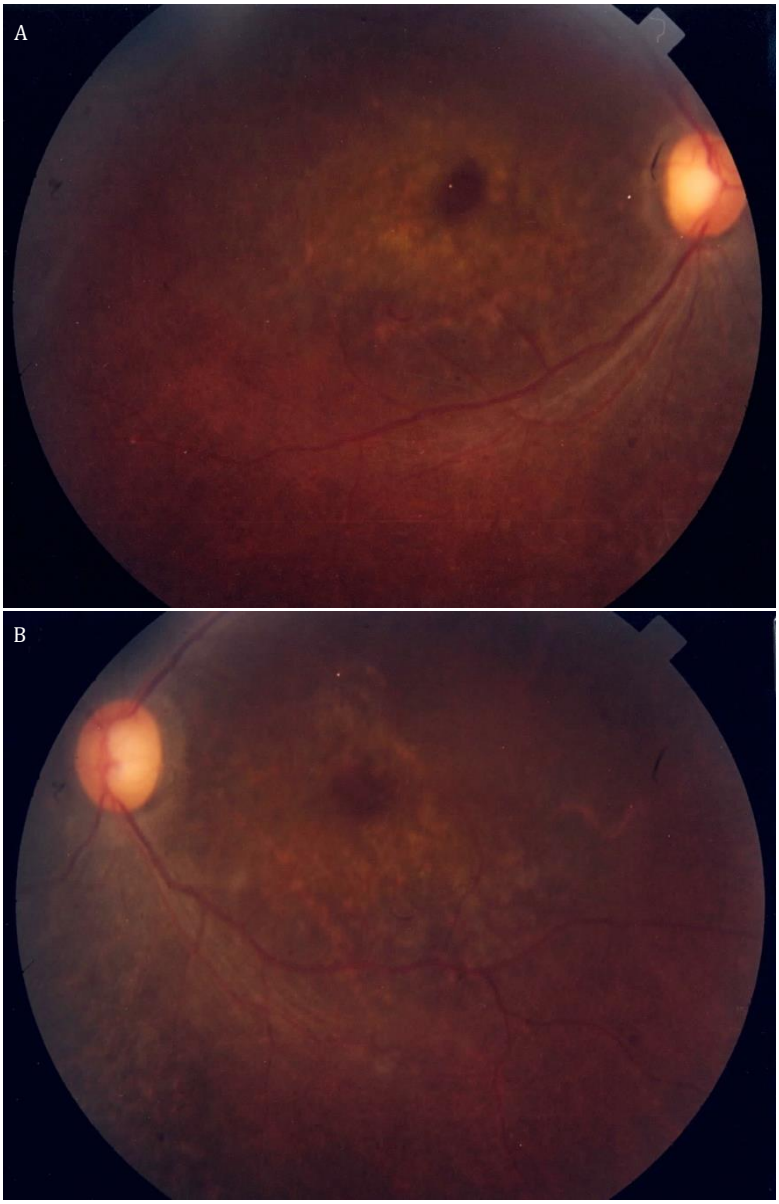

Fig. (1). (A). and **(B).** Fundus photographs of 39-year-old female show bilateral symmetrical peripapillary atrophy, bull's eye maculopathy, and attenuated retinal vessels.

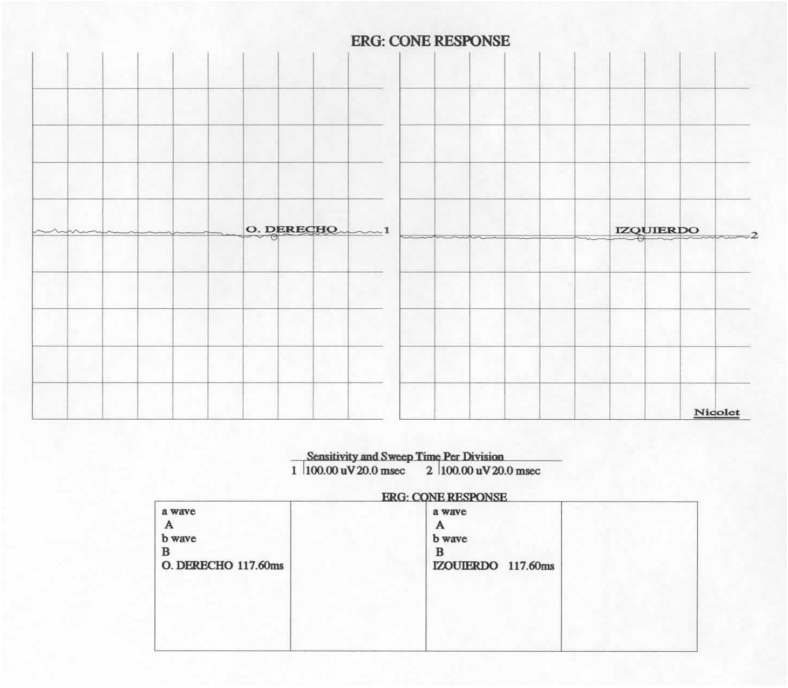

Fig. (2). Photopic ERG test reflects cone response is undetectable.

Full field electroretinogram (ERG) is the gold standard for diagnosis. Electroretinogram shows reduced cone and rod responses, the former being more severely affected (Figs. **2 - 4**). Electrooculogram (EOG) is usually abnormal (Fig. **5**) [1, 2, 11, 12]. Fluorescein angiography can detect an area of macular atrophy with hyperfluorescence due to a window defect, with or without the characteristic pattern of Bull's eye maculopathy (Fig. **6**) [12]. Autofluorescence imaging allows the visualization of an area of absence of RPE (that looks hypoautofluorescent) or RPE that is in distress (that looks hyper autofluorescent) which may enhance the visualization of RPE defects in these diseases. Visual fields reveal a concentric decrease of sensitivity with a central scotoma (Figs. **7** and **8**). Color vision tests show acquired intense dyschromatopsia [2, 10 - 12]. OCT demonstrates significant reduction in the thickness and structural changes in the outer layers of the retina in the central macula. Atrophy is evident, especially in the outer nuclear layer, the ellipsoid layer, and in the RPE (Fig. **9**). Visual acuity varies according to the degree to which the continuity of the ellipsoid layer is maintained. Eyes with a

Mitzy E. Torres Soriano

Dr. Mitzy E. Torres Soriano graduated with honors in medicine at the University of Carabobo, Maracay, Venezuela in 2001. Then in 2003 she began her postgraduate studies in Ophthalmology in Hospital Miguel Pérez Carreño (Caracas, Venezuela) where she also served as Chief Resident, and completed them in 2005. From 2006 to 2008, she did a fellowship in Retina and Vitreous in Asociación para evitar la Ceguera. Hospital Dr. Luis Sánchez Bulnes, in Mexico. She dedicates her clinical practice to the medical and surgical treatment of retinal and vitreous diseases.

She has taken many courses and attended numerous congresses on ophthalmology, and has also written various articles and book chapters. She provides review services to several science international journals about ophthalmology and contributes in retinal clinical research.

Gerardo García-Aguirre

Dr. Gerardo García-Aguirre graduated magna cum laude, obtaining his medical degree at the School of Medicine, Tecnológico de Monterrey, in Monterrey, Mexico in 2002, and his residency in Ophthalmology and Retina fellowship at Asociación para Evitar la Ceguera en México, in Mexico City. In 2008 he became an attending physician at the same hospital. He is author or coauthor of over 30 papers, 15 book chapters and one book in the field of ophthalmology.

Maximiliano Gordon

Dr. Maximiliano Gordon graduated in medicine from Universidad Nacional de Rosario, Rosario, Argentina, in 1999. He did an ophthalmology residency at Centro de la Vision, located in Rosario, between 2000 and 2002, and a fellowship in Retina and Vitreous at the Asociación para Evitar la Ceguera, at Hospital Luis Sanchez Bulnes, located in Mexico City, Mexico, between 2006 and 2008.

With more than 10 years of experience in clinical and surgical management of diseases of the retina and vitreous, he currently works as a retina specialist in Centro de la Vision Gordon-Manavella and as instructor in the residency program of the Retina department of Hospital Provincial del Centenario, in Rosario.

Veronica Kon Graversen

Dr. Veronica Kon Graversen attended Catholic University of Santiago de Guayaquil, School of Medicine where she graduated Summa Cum Laude. She was then accepted into one of the most prestigious ophthalmology training programs in Latin America at the Ophthalmology Institute Conde de Valenciana in Mexico city. She then completed a two-year Retina and Vitreous surgical fellowship at the Association to Prevent Blindness in Mexico (APEC), Luis Sanchez Bulnes Hospital, under the preceptorship of Hugo Quiroz Mercado.

Dr. Kon Graversen completed a second ophthalmology residency program at the University of North Carolina at Chapel Hill, where she also served as Chief Resident. She is eligible to be board certified in Ophthalmology. She has published numerous articles in peer-reviewed journals and has lectured at multiple international meetings. She recently moved to Denmark with her husband and is affiliated with Glostrup Hospital.
